and cases in the United States appear to cluster in the Midwest, particularly along the Mississippi and Missouri river areas.[43,81] Disease in humans usually results from inoculation of minor wounds by debris containing *S. schenckii*, and gardeners and nursery workers, forestry workers, miners, and other individuals exposed to contaminated plant materials are at higher risk for acquiring the disease.[15,19] Disseminated disease has been the initial presentation of some human immunodeficiency virus (HIV)–infected individuals.[2] Laboratory personnel working with the organism have become infected after incurring needle-stick injuries.[106] The large South African epidemic in the gold mines of Transvaal probably resulted from the miners' brushing against rotting timbers in the mines, and a cluster of cases that occurred after a brick-throwing incident in Florida was traced to *S. schenckii* in the packing straw of the bricks.[90,108] Contaminated hay was the source of one outbreak linked to a Halloween haunted house.[26] Pulmonary disease may result from inhalation of spores.[81] Uncommonly, transmission of disease from animals, particularly domestic cats with cutaneous disease, or from family members occurs.[28,35,39,85] One adult acquired the disease after being bitten by a squirrel,[91] and a young girl developed cutaneous disease after a rodent bite.[50] In South America, armadillo hunters are at risk for development of sporotrichosis, but it is acquired from the decaying plant debris in armadillo nests rather than from the animals themselves.[71] Cats have been implicated in ongoing outbreaks in Brazil.[7,37,95,96] Molecular typing of isolates can be useful in investigations of outbreaks.[18,74,75]

PATHOGENESIS AND PATHOLOGY

As indicated, the most common mode of acquisition of sporotrichosis is by inoculation of the organism into skin structures, although disease also may develop from inhalation of spores of the organism. The incubation period varies considerably, commonly ranging from 7 to 30 days after cutaneous inoculation but possibly as long as 6 months.[87] The disease usually remains localized; of the 2825 cases of sporotrichosis in the Transvaal mine epidemic, none had systemic spread.[108]

S. schenckii, similar to other yeasts, seems to bind specifically to the glycosphingolipid lactosylceramide, which is present on the cell surface of animal cells.[54] This mechanism may be one by which the organism establishes a foothold in the host. Cell-mediated immune responses probably are important for containment of infection. One study documented intact responses in patients with cutaneous forms of the disease, whereas patients with systemic sporotrichosis had impaired cell-mediated immunity.[80] This study is supported by the observation that systemic disease tends to occur in individuals with underlying diseases or conditions that alter cell-mediated immunity. More recently, deficiencies in Toll-like receptor 4 have been suggested as contributing to severity of sporotrichosis.[6,92] Specific virulence factors also may contribute to likelihood of disseminated disease.[3,6,105,118]

Histopathologic examination of primary cutaneous lesions usually reveals changes in the epithelium, with hyperkeratosis, parakeratosis, and pseudoepitheliomatous hyperplasia. Intraepidermal microabscesses may be seen as well. In more established lesions, the pathologic process involves the dermis and below, with inflammatory infiltrate extending perivascularly.[68] The classic lesion on microscopic examination is a granuloma with an asteroid body at the center, although this picture is not pathognomonic for sporotrichosis. The asteroid body is an antigen-antibody complex deposited on the surface of the organism and may consist of several forms.[67,117] Visualization of fungi in tissue sections often is difficult, even with special staining techniques, because of the paucity of organisms in tissue. They may be seen on Gram stain as gram-positive but irregularly staining bodies, sometimes as cigar-shaped, 3- to 5-μm yeast forms. Periodic acid–Schiff and silver stains probably are better suited for detection of fungi in tissue sections.[68,87] Immunohistochemical staining techniques may prove superior to standard methods.[73,78]

CLINICAL MANIFESTATIONS

Sporotrichosis can occur in cutaneous and extracutaneous forms; the cutaneous varieties account for approximately 80 percent of all cases.[87] These categories can be broken down further into the organ system involved (Table 204-1).

Cutaneous Sporotrichosis

Cutaneous disease with *S. schenckii* can be either lymphocutaneous or fixed cutaneous, the latter of which occurs less frequently. In lymphocutaneous cases, the initial lesion appears as a firm, slightly tender subcutaneous nodule. It progresses along local lymphatic channels, with multiple nodules appearing. The lesions typically enlarge and may ulcerate and suppurate (Fig. 204-1). Untreated, they may heal slowly during months or persist; recurrences are frequent. Differential diagnosis includes cutaneous nocardiosis, atypical mycobacterial disease, leishmaniasis, rosacea, syphilis, pyoderma gangrenosum, disseminated *Acanthamoeba* disease, and cutaneous manifestations of other fungal diseases.[23,61,84,104,115]

The fixed cutaneous form of the disease is just as the name implies, with no evidence of lymphatic spread. The primary lesions are identical to the lesions seen in the lymphocutaneous form. Although some researchers have

TABLE 204-2 **Summary of 42 Cases of Pediatric Sporotrichosis**

Duration of symptoms before diagnosis	3-10 weeks
Lymphatic involvement	28/47*
Culture positive	39/44*
Relapse after therapy	1/21*

*Numerator is number of patients positive; denominator is number of patients tested.
Data from references 13, 16, 21, 42, 69, 76.

suggested that sporotrichosis in children, compared with that in adults, is more likely to appear in the fixed cutaneous form, this theory has not been borne out in prior studies. Table 204-2 shows results from six reports of series of cases of sporotrichosis in children. The 60 percent rate for the lymphocutaneous form may not differ much from the 90 percent figure quoted for adults when one takes into account that many pediatric studies are reports of small numbers of cases and may have resulted from selection bias. A large series of patients from Peru documented a disproportionate number of children with facial lesions (86 of 143 children vs. 23 of 95 adults) but did not classify fixed versus lymphocutaneous forms by age.[79] Fixed cutaneous disease in children has been confused with impetigo.[13] A study from Peru also documented a predilection of children to develop lymphocutaneous lesions on the face and neck.[70] Risk factors for disease in children in this study included playing in fields, ownership of a cat, and residence in a house with dirt floors. Unusual dermatologic manifestations reported include molluscum-like lesions in a patient with alcoholic liver disease and Sweet syndrome in middle-aged women.[38,93]

Extracutaneous Sporotrichosis

Sporotrichosis occurring in extracutaneous sites either may be localized (related to an unusual area of trauma) or may represent disseminated disease. In the absence of trauma, the presence of extracutaneous sporotrichosis should raise suspicion of disseminated disease and consideration of immunodeficiency states. Overall, infection of bones and joints is the most common form of extracutaneous disease.[113] Sporotrichal arthritis usually is an indolent and slowly progressive disease that may occur with or without cutaneous or lymphatic disease, suggesting a hematogenous route of infection for most cases. Diagnosis generally requires synovial biopsy with culture to show the organism.[97,113] Two studies showed diagnostic delays averaging 17 and 25 months from the onset of symptoms.[8,20] Sporotrichal osteomyelitis usually occurs with concomitant arthritis, but isolated bone involvement has been recorded. Lytic lesions and periosteal changes are noted most frequently.[45,113]

Pulmonary sporotrichosis seldom occurs with cases of disseminated disease and probably develops after inhalation of spores, as with primary pulmonary histoplasmosis.[81] The presence of cavitary lesions in the upper lobes often leads to a diagnosis of tuberculosis, and fungal culture of sputum, bronchoscopic specimens, lung tissue, or gastric aspirate usually is needed to establish the diagnosis.[29,81,111] Pleural involvement is uncommon (3 of 47 cases in one review), and complications, such as massive hemoptysis, rarely occur.[31,49,81]

Sporotrichosis has been found to involve virtually every organ system in the body as part of disseminated disease.[113] Most commonly, underlying immunodeficiency states, such as diabetes, prolonged steroid therapy, alcoholism, immunosuppressive therapy, and acquired immunodeficiency syndrome (AIDS), are present.* In one Brazilian cohort of HIV-infected patients with sporotrichosis, 7 of 21 developed disseminated disease and 2 had meningitis.[36] Ocular and endocardial infection has been reported as well.[103] Disseminated disease, including meningitis, also has been reported as part of immune reconstitution syndrome in AIDS patients.[40,47] Fungemia in the absence of disseminated disease has been documented in one otherwise healthy adult with a lysis-centrifugation blood culture system, and laryngeal and cutaneous sporotrichosis have been reported in a healthy child.[60,62] Dissemination in patients with neoplasia seldom occurs.

DIAGNOSIS

A high index of suspicion is necessary to establish the diagnosis of sporotrichosis. In the largest outbreak in the United States, which occurred in 1988 among horticulturists and forestry workers, only 15 percent of cases were diagnosed at the time of initial presentation to a physician.[17] Culture is the "gold standard" for diagnosis of sporotrichosis. Although organisms occasionally are seen

*References 1, 32, 44, 51, 55, 63, 102, 107, 113, 116.

on pathologic specimens, the yield is low enough to render biopsy unnecessary. If the diagnosis is suspected, scrapings of cutaneous lesions for culture should be sufficient to establish the diagnosis.[87]

A skin test antigen has been available for many years, but as with the histoplasmin skin test for histoplasmosis, it is useful mainly as an epidemiologic tool. Polymerase chain reaction may prove useful for diagnosis in the future.[56] Serodiagnosis has been explored in a few studies. Immunoprecipitation or commercially available slide latex agglutination can be useful when material for culture is difficult to obtain or cultures are negative, such as with sporotrichal meningitis.[24,98] Similarly, an enzyme-linked immunosorbent assay has been used for diagnosis. Antibody titers in cerebrospinal fluid tend to decrease with successful therapy, and such tests might prove useful for monitoring of response to therapy.[9,98] Western blotting has been used to detect sporotrichal antibody.[99] Using a crude antigen preparation, Scott and Muchmore[99] determined that detection of antibody to three antigens, 32 kDa, 40 kDa, and 70 kDa, seems to be sensitive and specific for diagnosis of active sporotrichosis. Patients with extracutaneous disease seemed to form antibody to a greater number of *S. schenckii* organisms than did patients with cutaneous disease. Further studies of the immune response in sporotrichosis should enable development of better serodiagnostic tests than those that now are routinely available.

TREATMENT AND PROGNOSIS

Sporotrichosis may resolve spontaneously, but treatment is indicated in most circumstances.[5,82] The Infectious Diseases Society of America has published practice guidelines for management of patients with sporotrichosis.[59]

Heat applied to the site of cutaneous disease has been reported anecdotally to cause resolution of lesions in patients in whom medical therapy was contraindicated.[41,88,109] One prospective study showed good results with use of benzene pocket warmers for heat therapy of facial lesions in children.[52] Surgical removal of infected skin and soft tissue has been used, but skin grafting may be required.[12] This form of treatment usually is unnecessary with the availability of medical management except possibly for some cases of pulmonary infection (particularly if it is confined to one lobe) and other extracutaneous disease.[20,45,81] Hyperthermia remains an option for treatment of sporotrichosis in pregnancy, in situations in which other agents may be contraindicated.[57]

A saturated solution of potassium iodide (SSKI), a proteolytic agent for which the mechanism of action against sporotrichosis is unclear,[58,65] can be used for uncomplicated sporotrichosis. The in vitro growth of *S. schenckii* is not inhibited appreciably by iodide, but free iodine has a marked inhibitory effect on growth.[112] The small amount of free iodine in a saturated solution of potassium iodide may be sufficient to cause resolution of disease. The pediatric dosage of a saturated solution of potassium iodide is empirical; it usually is given three times daily in juice or milk, starting at a low dose (e.g., 1 to 2 drops per year of age) and increasing the dose during the course of several days to a maximum of 30 to 40 drops per dose.[16,69,76] For younger children, lower dosages may be acceptable.[69,83] Treatment is continued until a few weeks after all lesions have resolved. Adverse reactions, such as salivary gland swelling, excessive lacrimation or salivation, nausea, vomiting, and abdominal pain, may resolve with temporary cessation of therapy followed by reinstitution at a lower dosage. SSKI currently is only an alternative treatment for lymphocutaneous and cutaneous forms of the disease.[57]

In vitro susceptibility testing is not used widely, and results may not always agree with clinical response.[89,110] The Clinical and Laboratory Standards Institute has proposed a microdilution test, whereas the European Committee for Antimicrobial Susceptibility Testing uses a similar assay with a different inoculum and test medium.[6] Breakpoints have not been established.

Itraconazole, an oral azole derivative, is the drug of choice for treatment of cutaneous, lymphocutaneous, and osteoarticular forms of sporotrichosis.[11,53,54,57,101] Restrepo and colleagues[86] showed clinical cures in all 17 patients with cutaneous forms of sporotrichosis treated with itraconazole (100 mg/day), with no major side effects. Borelli[10] reported a treatment failure, however, in a patient treated with 100 mg/day, who subsequently responded when the dose was increased to 200 mg/day. Systemic disease also has been treated with itraconazole with favorable clinical responses, although all information is from cases in adults.[4,64,77,101,114]

Intravenous amphotericin B remains the drug of choice for treatment of patients with disseminated or severe sporotrichosis.[57,66,113] Duration of therapy in children has not been studied, but recommendations are to begin with liposomal amphotericin B at 3 to 5 mg/kg/day, with stepdown to itraconazole after clinical improvement to complete 12 months of total treatment.[59] On occasion, intra-articular amphotericin B is used to treat sporotrichal arthritis if response to other therapy is poor.[27] Amphotericin B therapy in patients with pulmonary sporotrichosis is less effective than with other forms of sporotrichosis, which has prompted many clinicians to use a combined medical-surgical approach.[59,81] Itraconazole is an alternative therapy and may be useful for long-term suppression.[59] Amphotericin B seems to be effective in treating sporotrichal meningitis when it is given early in the course of the disease, but adjunctive therapy with flucytosine or rifampin might be helpful.[97] Itraconazole and fluconazole also may have roles in treating meningitis.[53,59] Immunosuppressed individuals may require lifelong suppressive therapy with itraconazole to prevent recurrence, depending on the degree of immunosuppression and severity of disease.[59]

S. schenckii does not seem to be particularly susceptible to ketoconazole in vitro, and clinical experience with ketoconazole treatment of sporotrichosis has been mixed.[14,22,100] Possibly, relatively large doses of ketoconazole are needed to produce a good clinical response. Terbinafine, an allylamine, has looked promising in clinical studies.[33,34,53] Posaconazole has looked promising in a murine model of sporotrichosis.[30]

Prognosis for cutaneous forms of disease is excellent, but the extracutaneous forms are associated with significant morbidity and mortality, in part related to the underlying conditions predisposing these patients to disseminated disease. Many cases of osteoarticular disease result in permanent disability.[20]

PREVENTION

The key to prevention of sporotrichosis is the elimination of exposure to the organism, particularly with regard to skin surfaces and mucous membranes. Usually, elimination of exposure can be accomplished by the use of protective clothing during high-risk activities, such as working with sphagnum moss or other decaying, moist plant material.[15,17] Nursery workers should be educated about the hazards and early signs of sporotrichosis, and physicians and veterinarians should be aware of the uncommon circumstances of spread of the infection from family members and domestic cats. The epidemic in the Transvaal gold mines was stopped when timbers in the mine shafts were sprayed with a fungicide.[108] Although reporting of individual cases of sporotrichosis is not required in the United States, reporting of clusters of cases can aid epidemiologic investigations and stop the spread of the disease.

CHAPTER 205

Mucormycosis and Entomopthoramycosis (Formerly Zygomycosis)

Theoklis E. Zaoutis • William J. Steinbach

The diseases originally known as mucormycosis or phycomycosis were previously renamed *zygomycosis*, in an effort to group uncommon but frequently fatal mycoses caused by fungi of the phylum Zygomycota. However, molecular phylogenetic analyses confirmed the phylum to be polyphyletic, and those taxa conventionally classified in Zygomycota are now distributed among the new phylum Glomeromycota and four subphyla.[65] Because the name *zygomycosis* was based on the phylum Zygomycota, this new classification alters the name of the clinical diseases. Instead, it is best to now use the names *mucormycosis* to refer to disease caused by members of the order Mucorales (not by organisms from the genus *Mucor* as the name might suggest) and *entomophthoramycosis* for disease caused by species from the order Entomophthorales. Therefore, the term *zygomycosis*, which has historically often been used incorrectly as a synonym of only mucormycosis, should not be used. As molecular phylogenetics continues to progress, these taxonomic definitions and clinical names may be subject to further change.

Organisms of the class Zygomycetes were first noted to cause disease in humans in publications from the 1800s. Plataut[102] is credited with the first description of mucormycosis in humans in his paper "Mycosis Mucorina." In this German language manuscript, he described a case of disseminated mycosis in a cancer patient. The first English-language description of the disease appeared in 1940 when Wade[149] described a case of cutaneous mucormycosis infection of the face.

The class Zygomycetes is divided into two orders, the Mucorales and the Entomophthorales.[112] The Mucorales are responsible for the majority of disease seen in humans, predominately affecting immunocompromised hosts and often characterized by a rapidly evolving clinical course with tissue destruction and invasion of blood vessels. The mycoses caused by Entomophthorales historically have been limited to immunocompetent patients residing in tropical and subtropical areas of the world. Infections caused by Entomophthorales are usually chronic, subcutaneous, and limited without blood vessel invasion.[112] This chapter will focus on the more relevant infections caused by Mucorales, with a brief description of infections caused by Entomophthorales.

THE ORGANISMS

The organisms of the class Zygomycetes are ubiquitous in nature and have a wide geographic distribution. The class consists of two orders—Mucorales and Entomophthorales—each containing several species reported to cause disease in humans (Fig. 205-1).[112] The most common causative Mucorales organisms in humans are the *Mucor*, *Rhizopus*, *Lichtheimia* (formerly *Absidia*), and *Rhizomucor* genera, but other genera in the order include *Saksenaea*, *Cunninghamella*, and *Apophysomyces*. These organisms grow readily on common laboratory media but are inhibited by cycloheximide. Growth of members of Mucorales on solid media demonstrates rapid growth of woolly colonies, often with spores seen as tiny dark dots to the naked eye. Hyphae characteristically are large (10 to 30 μm in diameter), nonseptate, and often twisted or ribbon-like. The lack of septation and the tendency of hyphae to branch at right angles usually serve to distinguish them from *Aspergillus* spp., which are septate, smaller, and branch at acute angles.[3] Genera usually are differentiated from one another by examination of mycelia. Speciating the members of Zygomycetes is often difficult. The Entomophthorales organisms that cause human infection to date are confined to two genera, *Conidiobolus* and *Basidiobolus*. Growth of members of Entomophthorales also occurs readily on solid media but appears as flat, gray, or pale yellow waxy colonies with velvety white mycelia on the surface.[112] The hyphae often are septate.

EPIDEMIOLOGY

All members of Zygomycetes are found in all parts of the world, regardless of climate or other factors. Most human disease caused by members of Mucorales is concentrated in North America, perhaps because of a concentration of immunocompromised hosts.[8] Infections caused by the Entomophthorales genera *Basidiobolus* and *Conidiobolus* occur predominantly in Africa, India, and the Far East, although a few cases have been reported in North and South America.[112]

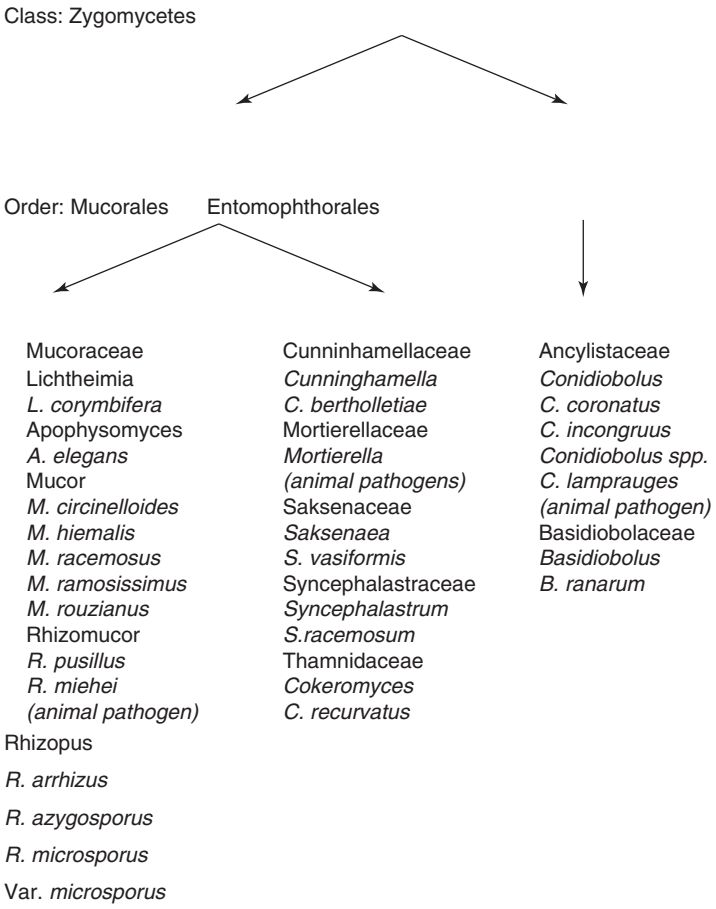

FIGURE 205-1 ■ **Classification of zygomycetes.** (From Ribes JA, Vanover-Sams CL, Baker DJ. Zygomycetes in human disease. *Clin Microbiol Rev* 2000;**13**:236-301.)

These fungi are commonly found in soil, in decaying organic material such as vegetation, bread, seeds and fruits and in manure. Many of them are animal pathogens. Members of Mucorales are also occasionally isolated from the hospital environment.[58,61,112,154,157] Studies have suggested a relationship between activities involved in hospital construction and development of mucormycosisin immunocompromised hosts.[61,118,157] *Rhizopus* spp. frequently are found in moldy bread and fruits.[112] Members of Entomophthorales commonly are found in feces of reptiles and other animals, decaying vegetable matter, and some are insect pathogens.[112]

The ubiquitous nature of these organisms, coupled with the paucity of human disease associated with them, is strong evidence for their relatively saprophytic characteristics. Mucormycosis and entomophthoramycosis infections are rare, occurring at an annual rate of 1.7 infections per million population in the United States.[109] In the past decade, however, the frequency and incidence of mucormycosis has increased, particularly among hematopoietic stem cell transplant (HSCT) recipients and patients with hematologic malignancies (Fig. 205-2A and B).[36,59,80] Despite this increase over the last decade, mucormycosis and entomophthoramycosis were seen at autopsy in 1.9 percent of patients dying of malignancy, contrasting with the high incidence of aspergillosis at autopsy (19.6%) at the same center.[60] The incidence of mucormycosis complicating HSCT was 2.5 percent in one study, and it may be less common than other molds because evaluation of indoor environments shows Zygomycetes are rarely isolated.[72] A review of 1500 patients who underwent HSCT over the span of 26 years at one center found that only 0.9 percent of patients had mucormycosis.[89] In the largest systematic review of reported cases, *Rhizopus* and *Mucor* spp. were the most commonly reported causative organisms, identified in 47 percent and 18 percent of cases, respectively.[116] A review of 157 published cases of pediatric mucormycosis revealed a similar distribution of species causing infection in both children and adults.[162] The overall cost of mucormycosis to the U.S. health care system is estimated at $50 million/yr.[44] The multicenter Transplant-Associated Infection Surveillance Network (TRANSNET) found that among 1208 invasive fungal infections identified among 1063 transplant recipients, of the mold infections, mucormycosis was responsible for only 2 percent of cases, in contrast to invasive aspergillosis (19%) and non-*Aspergillus* molds (8%).[99] The time to diagnose mucormycosis was a median of 312 days after transplantation.

A large European registry of 230 cases of mucormycosis from 2005 to 2007 found the most common underlying conditions to be hematologic malignancies (44%), with diabetes mellitus in 9 percent of cases. Of the cases, the majority (34%) were due to *Rhizopus* spp., with *Mucor* spp (19%) also identified frequently. On multivariate analysis, treatment with amphotericin B and surgery were associated with survival.[128] A large retrospective French study of 101 cases also between 2005 and 2007 found that

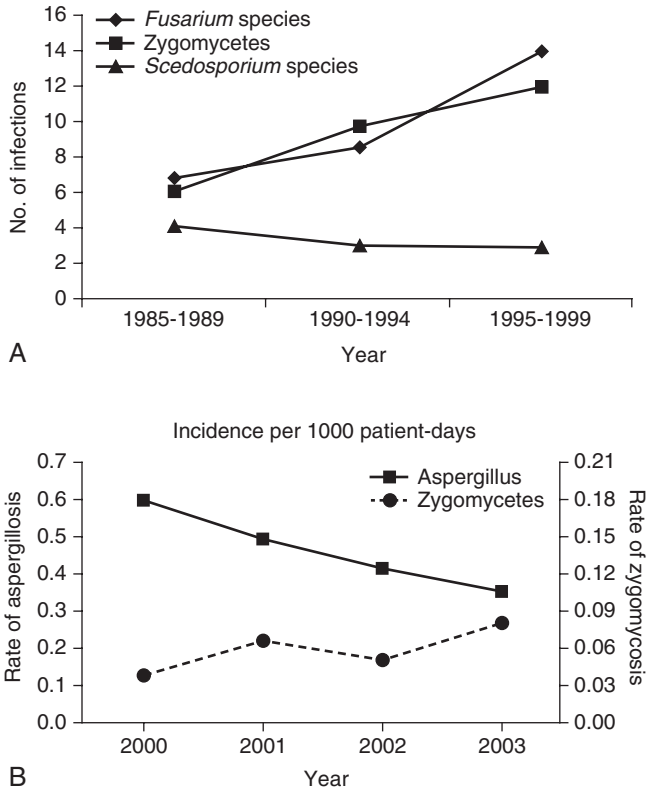

FIGURE 205-2 ■ **A,** Changing frequency of non-*Aspergillus* moulds in blood and marrow transplantation recipients at Fred Hutchinson Cancer Research Center (Seattle, Wash), 1985-1999. **B,** Changing spectrum of *Aspergillus* and Zygomycetes at M.D. Anderson Cancer Center (Houston, Tex). (**A,** from Marr KA, Carter RA, Crippa F, et al. Epidemiology and outcome of mould infections in hematopoietic stem cell transplant recipients. *Clin Infect Dis* 2002;**34**:909-17. **B,** from Kontoyiannis DP, Lionakis MS, Lewis RE, et al. Zygomycosis in a tertiary-care cancer center in the era of *Aspergillus*-active antifungal therapy: a case-control observational study of 27 recent cases. *J Infect Dis* 2005;**191**:1350-60.)

again hematologic malignancies were the most common underlying condition (50%) and that the median time for mucormycosis was 8.8 months after disease occurrence. The main fungal species isolated were *Rhizopus oryzae* (32%) and *Lichtheimia* spp. (29%). Specifically, *R. oryzae* was found in 85 percent of rhinocerebral forms, in contrast to only 17 percent of nonrhinocerebral disease.[68] In a smaller registry of 41 patients with mucormycosis, the most common underlying conditions were malignancies (63%), diabetes mellitus (17%), and solid-organ transplantation (10%). The lung was the most commonly affected organ, and dissemination occurred in 15 percent of patients.[120] A retrospective analysis of children with mucormycosis (2003 to 2010) found 156 cases and noted that the prevalence did not significantly increase over time. Consistent with adult data, the most common underlying condition was malignancy (58%).[104]

Mucormycosis commonly presents as an opportunistic infection in patients with underlying risk factors. Predisposing risk factors include immunosuppression, metabolic disorders, breakdown of skin or soft tissue integrity such as in burn patients or surgical patients, and prematurity (Table 205-1).[58,60,116,162] The most commonly reported underlying conditions in both adults and children are diabetes mellitus and neutropenia.[60,116,162] Recent evidence has suggested that the increasing use of voriconazole as prophylaxis and as empirical, preemptive, and targeted therapy for invasive aspergillosis is associated with an increased risk for mucormycosis.[47,59,81,127] One hypothesis is that voriconazole, because of its lack of activity against Zygomycetes, has exerted selection pressure favoring the emergence of mucormycosis.[157]

TABLE 205-1 Underlying Diseases Commonly Associated with Increased Risk for Mucormycosis

Pediatric-Specific Risk Factors
Prematurity[162]
Methylmalonicaciduria
Malnourishment
Risk Factors Seen in Both Adults and Children[116,162]
Neutropenia or neutrophil dysfunction
Diabetes mellitus
Malignancy
Organ transplantation
Corticosteroid therapy
Human immunodeficiency virus infection
Deferoxamine therapy
Intravenous drug use
Trauma or surgery
Burns

MUCORMYCOSIS

Pathogenesis and Pathology

Mucormycosis usually is acquired by humans after inhalation of spores from environmental sources, and the organisms may colonize the sinuses and nasopharynx of some patients.[112] Occasionally, mucormycosis results from cutaneous inoculation of spores secondary to trauma, as has occurred with contaminated elastic adhesive tape[28,38,112] and ingestion of fermented milk or dried bread products.[69,93] After the inhalation of airborne spores, primary infection usually develops in the upper and lower respiratory tract and later by contiguous or hematogenous dissemination. Disseminated disease most commonly arises from the lungs and spreads hematogenously to the central nervous system (CNS), kidneys, gastrointestinal tract, and heart. Dissemination also can occur from cutaneous or subcutaneous sites of infection.[28,38,132] Person-to-person transmission has not been documented.

The immune status of the host is fundamental to production of disease. In normal hosts, Zygomycetes are killed by mononuclear cells and neutrophils via the generation of oxidative metabolites and cationic peptide defensins.[29,150,152] The neutrophil appears to be the primary component of the immune response against these organisms and may serve to prevent germination of inhaled spores.[29] Both neutropenia and qualitative deficiencies of neutrophil function are associated with an increased risk for mucormycosis.[19,132] In addition, corticosteroid treatment impairs the ability of macrophages to

prevent germination of the spores.[151] Mucormycosis reported in patients with acquired immunodeficiency syndrome (AIDS) tends to occur in intravenous drug users and may reflect direct inoculation as the risk factor, rather than the immunodeficiency itself.[90,130] Disease may follow a less fulminant course in patients with AIDS in contrast to other immunocompromised populations.[9]

Diabetes mellitus, in particular diabetic ketoacidosis, is the most common underlying disease in patients with mucormycosis.[57,58,116] Serum from patients with diabetic ketoacidosis does not inhibit the growth of *Rhizopus* spp., but serum from those same patients after treatment of the ketoacidosis does show inhibitory properties similar to those of normal human serum.[4,19,37,112] Furthermore, hyperglycemia and acidosis, commonly seen in diabetic patients, are known to impair the ability of phagocytes for chemotaxis and to kill the organisms by both oxidative and nonoxidative mechanisms.[19]

Iron levels in serum also may play a role in the pathogenesis and immune response to the organisms. Patients treated with the iron chelator deferoxamine have a markedly increased risk for invasive mucormycosis, as demonstrated by the tendency for deferoxamine therapy to result in progression of both natural and experimental mucormycosis.* This phenomenon seems to occur commonly, particularly in patients undergoing hemodialysis.[10,11,160] Studies in experimental animals suggest that deferoxamine may serve as a siderophore for *Rhizopus* spp., with resultant increased fungal growth and increased mortality in a guinea pig model.[12,27,145] A phase II clinical study found that patients with mucormycosis treated with deferoxamine had a higher mortality at 90 days, therefore not supporting a role for initial adjunctive deferoxamine therapy.[134] In diabetic patients, the presence of systemic acidosis can lead to elevated levels of serum iron, likely as a result of the release of iron from binding proteins.[4] In vitro data conflict, however, on the exact effects of iron or deferoxamine on promoting the growth of members of Mucorales.[95] Much remains to be understood about the pathogenesis of mucormycosis, and a unifying concept will have to incorporate the effects of steroids, acidosis, and iron on host neutrophils and macrophages in failing to suppress fungal replication.

The hallmark of histologic examination of mucormycosis is vascular invasion with resultant thrombosis and tissue necrosis and accompanying acute and chronic inflammation.[15,46,132] Most of the clinical findings of progressive disease can be related to these effects on blood vessels. Septic emboli may affect all parts of the body. Perineural invasion also occurs commonly.[35] In the rhinocerebral form, the disease may progress along nerve roots during intracranial spread. Although relatively sparse, hyphal forms may be seen in tissue on routine hematoxylin and eosin staining more commonly than with silver or other special fungal stains (Fig. 205-3).[114]

Clinical Manifestations

The clinical forms of mucormycosis are best considered by type of organ system involvement (Table 205-2). The primary site of infection at the time of initial diagnosis varies as a function of the host population (Table 205-3). Rhinocerebral, cutaneous, and pulmonary diseases are the most common clinical manifestations of mucormycosis.[116] Other forms of invasive mucormycosis include gastrointestinal, disseminated, and other rare presentations.[58,116]

Miscellaneous

Acute Rhinocerebral Mucormycosis

The acute rhinocerebral form of mucormycosis, including sinus and sino-orbital infections, is the most common presentation of mucormycosis and occurs most often in the setting of diabetes mellitus.[60,116] Rhinocerebral mucormycosis spreads from the nares, palate, or sinuses to the paranasal sinuses, and then to the retro-orbital region and brain by hematogenous spread. Symptoms include facial pain and headache; physical examination reveals brownish, blood-tinged nasal discharge; black eschar on the palate; proptosis; or cranial nerve involvement.[33] Involved tissues become red, then violaceous, and finally black as vessels are thrombosed and tissues undergo necrosis. Extension into the periorbital region can be manifested as proptosis or orbital edema, and ocular or optic nerve involvement can be suggested by pain, blurring, or loss of vision.[131] Initial symptoms of invasive rhinocerebral disease include bloody nasal discharge,[112] seizures,[94] and cerebrovascular accident.[83] The mortality rate for rhinocerebral disease is greater than 50 percent.[116]

TABLE 205-3 **Patterns of Zygomycosis by Host Population**

Predisposing Condition	Predominant Sites of Infection (in Order of Frequency)
Diabetes mellitus	Rhinocerebral, pulmonary, sino-orbital cutaneous
Malignancy with neutropenia	Pulmonary, sinus, cutaneous, sino-orbital
Hematopoietic Stem Cell Transplantation	Pulmonary, disseminated, rhinocerebral
Solid-organ transplantation	Sinus, cutaneous, pulmonary, rhinocerebral, disseminated
Intravenous drug use or abuse	Cerebral, endocarditis, cutaneous, disseminated
Malnutrition	Gastrointestinal, disseminated
Deferoxamine-based therapy	Disseminated, pulmonary, rhinocerebral, cerebral, cutaneous, gastrointestinal
No underlying condition	Cutaneous, pulmonary, sino-orbital, rhinocerebral, gastrointestinal
No underlying condition	

Kontoyiannis DP, Lewis RE. Invasive zygomycosis: update on pathogenesis, clinical manifestations, and management. *Infect Dis Clin North Am* 2006;**20**:581-607.

FIGURE 205-4 ■ Cutaneous zygomycosis in a child with neutropenia.

Cutaneous Mucormycosis

Cutaneous mucormycosis represents approximately 20 percent of reported cases in adults and a slightly higher proportion of pediatric cases.[116,162] Primary cutaneous infection usually occurs at the site of trauma, burns, or adhesive dressings or invasive procedures in immunocompromised hosts.* Among neonates, the skin is the most common point of entry, with involvement of adhesive tape, monitor leads, or central venous access sites predominating. Premature infants represent most of the neonatal cases, and the overall mortality rate reported in the literature is 75 percent.[75,96,115] Secondary cutaneous disease results from hematogenous dissemination.[56] Primary disease may be very invasive locally and by direct extension affect adjacent bone and tissue. With vessel invasion, frankly disseminated disease may arise.

Primary cutaneous disease causes lesions that appear erythematous and indurated and progress to form black eschars (Fig. 205-4). In contrast, cutaneous disease arising from disseminated disease usually manifests in patients as nodular subcutaneous lesions that may ulcerate.[112] Cutaneous mucormycosis can be evidence of disseminated disease, but primary cutaneous mucormycosis associated with occlusive bandages, burns, or wounds rarely extends beyond local involvement.[49] Most cutaneous cases are caused by *Rhizopus* spp. and manifest with lesions that typically are black necrotic ulcers surrounded by erythematous and indurated painful cellulitis.[50] There can be rapid progression and skin necrosis caused by hyphae invading the vasculature and causing tissue infarction.[73] Cutaneous mucormycosis should be considered when skin necrosis continues despite administration of appropriate antibiotics.[98]

Pulmonary Mucormycosis

Pulmonary mucormycosis may develop as a result of inhalation or by hematogeneous or lymphatic spread. The clinical manifestations of pulmonary mucormycosis are similar to the manifestations of invasive pulmonary aspergillosis and often are indistinguishable.[18] Mucormycotic pneumonia typically develops in severely immunocompromised patients, such as patients with malignancy and neutropenia,[80,89,132] but it also has occurred in patients with juvenile diabetes mellitus and in normal hosts.[20,52,116] Patients with pulmonary mucormycosis often present with fever, cough, chest pain, and rapidly progressive dyspnea.[138] Angioinvasion results in necrosis of lung tissue, which may lead to cavitation and hemoptysis. Massive pulmonary hemorrhage may result from vascular erosion.[41,156] Chest radiographs and computed tomography (CT) scans may reveal a lobar pneumonia pattern, isolated masses, nodular disease, cavitation, or wedge-shaped areas of infarction.[55,79,84,138] Because of the lack of inflammatory cells that are capable of infiltrating the lung in neutropenic patients, however, radiography may not be dramatically abnormal.

A review of 58 solid-organ transplant recipients with mucormycosis found that pulmonary mucormycosis developed in 53 percent of the patients at a median of 5.5 months after transplantation. Those patients with disseminated disease most commonly had cutaneous soft tissue involvement, but the brain was not involved. The mortality at 90 days after treatment was over 45 percent.[135] Distinguishing pulmonary mucormycosis from invasive pulmonary aspergillosis is a clinical challenge. In patients with hematologic malignancies, clues for distinguishing pulmonary mucormycosis are the presence of concomitant pansinusitis, a history of antifungal prophylaxis with *Aspergillus*-active agents such as voriconazole and echinocandins, and possibly the repeated absence of detectable

*References 22, 38, 56, 142, 158, 159.

Aspergillus galatomannan antigen in serum. In addition, the presence of multiple nodules (>10) and, to a lesser degree, pleural effusions on CT scans favors the diagnosis of pulmonary mucormycosis over invasive pulmonary aspergillosis in patients with cancer.[18] Some atypical presentations of pulmonary mucormycosis include chronic infection with constitutional symptoms in relatively immunocompetent hosts.[84] Rarely, fungus balls have been noted within a preexisting lung cavity.[112] Hypersensitivity pneumonitis caused by *Rhizopus* spp. has been described in farm workers as well as Scandinavian sawmill workers (so-called wood trimmer disease).[31] The disease usually is fulminant, but may be milder in hosts with less severe immunocompromise.

Gastrointestinal Mucormycosis

Gastrointestinal involvement probably results from ingestion of fungal spores, from either the environment or colonized upper airways. Occasionally, hematogenous or direct extension routes result in intestinal tract involvement. Malnutrition, prematurity, uremia, and underlying gastrointestinal disease, such as typhoid fever or amebiasis, are predisposing factors.[74,85,87,93] Gastrointestinal mucormycosis is the most common clinical manifestation among neonates, representing two thirds of neonatal cases.[162] Most gastrointestinal disease in neonates is seen in premature neonates, some occurring in association with progressive necrotizing skin lesions and others manifesting with necrotizing entercolitis.[143,161] All sites along the intestinal tract can be involved, with the stomach and colon being the most common sites.[93] Nonspecific abdominal pain with hematemesis, hematochezia, or melena may occur. Dissemination to other sites may occur by hematogenous routes. Perforation after bowel wall necrosis is common. Diagnosis usually is made at autopsy.

Disseminated Mucormycosis

Disseminated mucormycosis occurs in the most severely immunocompromised patients and usually is diagnosed after death.[49,146] Clinical findings are nonspecific, and a high index of suspicion and readily accessible tissue for biopsy are needed to establish the diagnosis. The pulmonary system is affected most commonly, followed by the CNS, but virtually any organ can be involved. A subacute form of disseminated disease with a protracted but fatal course has been reported.[97] The combination of severe immunocompromise and subtle clinical findings renders this form of mucormycosis the most difficult to treat.

Miscellaneous Forms of Mucormycosis

A variety of case reports of mucormycosis involving isolated areas of the body are found in the literature and include reports of endocarditis,[86,119,163] brain abscess,[116] peritonitis,[16,91,103] osteomyelitis,[32] mediastinitis,[82] tracheitis,[124] corneal infection,[139] otitis externa,[139] superior vena cava syndrome,[14] and renal disease.[77] Common to these disease manifestations is some type of local accidental or surgical site that results in ready access for invasion of fungal organisms. Outcome varies highly and depends on the underlying condition of the host as well as the extent of disease.

Diagnosis

The presence of Zygomycetes in clinical specimens need not always represent clinically significant isolates. The spores from asexual reproduction are easily airborne and may be laboratory contaminants of culture medium or a result of oral ingestion in food or nasal inhalation of air before patient sampling. A positive culture linked to hyphal identification in cytologic specimens or tissue sections is considered diagnostic.[5,112] One study showed that the isolation of Zygomycetes from a patient with malignancy with no risk factors or clinically evident infection probably represents colonization; however, the pretest probability of a culture positive for Zygomycetes in a patient with leukemia was high.[60]

In most patients, the clinical presentation is assumed to be invasive aspergillosis, and in one series of 185 cases of disseminated mucormycosis, the correct diagnosis was made before death in only 17 cases.[49] In the largest single-center review of mucormycosis, chest radiographs were abnormal in all patients with pulmonary mucormycosis, showing patterns such as focal consolidation (30%), cavitation (24%), widespread infiltrates (24%), or nodules (18%).[60] Cavitation is a common finding on chest radiograph, but the "air crescent sign" is seen less frequently than in patients with invasive aspergillosis. In acidotic patients, pulmonary findings mostly manifest as lobar consolidation that may cavitate to form a lung abscess.[21] In one series, most manifestations in patients with pulmonary involvement were nodular or cavitary lesions.[89]

Noninvasive diagnostic procedures for mucormycosis are nonspecific, and a tissue diagnosis must be sought, even in situations in which other infectious agents have been isolated. Cultures of blood and bodily fluid rarely detect the disease. Immunofluorescent antibody staining of formaldehyde-fixed tissue is available through the mycology section of the Centers for Disease Control and Prevention, which might be helpful in confirming a suspected diagnosis.[33,49] Many specimens, including blood, sputum, gastric fluid, or nasal swabs, are either difficult to culture or of no diagnostic value, and invasive mucormycosis is correctly diagnosed with tissue biopsy.[33]

Antemortem respiratory tract specimens from autopsy-confirmed cases found 0/8 positive results in patients, including blood, urine, and cerebrospinal fluid cultures.[101] Cultures of lower respiratory tract specimens, including bronchoalveolar lavage and sputum specimens, were negative for mucormycosis in 75 percent of cases of histopathologically proved pulmonary mucormycosis, possibly owing to the high incidence of concomitant pulmonary infections.[60] Pulmonary mucormycosis has been diagnosed by fine-needle aspiration,[6] and an analysis of 87 cases of mucormycosis revealed that 40 percent of pulmonary disease was diagnosed by transbronchial biopsy and 20 percent required open lung biopsy or surgical resection for diagnosis.[71]

Serologic diagnostic tests for detecting mucormycosis are not clinically useful. Antibody tests lack specificity, whereas several antigen detection systems have been used in tissue specimens. Very few molecular techniques are in use for establishing the diagnosis of mucormycosis, and techniques that are available are still experimental. Polymerase chain reaction amplification of the 18S rRNA sequences may be useful in epidemiologic studies of outbreaks, but little is currently being offered for primary diagnosis.[112] Primers from ribosomal DNA for those Zygomycetes most implicated in clinical infection have been designed for use in a polymerase chain reaction assay for rapid and accurate identification.[113,148]

Treatment

Of overall great importance is the combination of early and aggressive surgical excision of the necrotic lesions, restoration of immune function, and intense antifungal therapy. Because tissue infarction is a prominent feature, removal of devitalized tissue is critical because antifungals alone, especially in the setting of continued immunosuppression, will not elicit cure.[72,101] All necrotic-appearing tissue should be removed, and often patients require repeated surgical procedures for removal of devitalized tissue. Surgical débridement alone may be sufficient to cure localized cutaneous disease.[106]

Currently, the recommended antifungal therapy for mucormycosis is amphotericin B, given at maximal dosages of 1 to 1.5 mg/kg/day, based on the individual's tolerance of side effects.[58] Amphotericin B lipid complex also has been used successfully,[100] including success with doses from 3 to 14 mg/kg/day, but there was no pattern of improved response in relation to dosage,[126] which correlates with the comparison of no advantage with 10 mg/kg versus 3 mg/kg of liposomal amphotericin B against invasive aspergillosis.[23] In a study of 41 cases, initial treatment with liposomal amphotericin B was associated with improved outcome ($p = 012$) and survival ($p = .004$) in contrast to initial treatment with amphotericin B, deoxycholate, or posaconazole.[120] Whether lipid formulations of amphotericin B definitively confer any advantage over conventional amphotericin B for mucormycosis is unclear,[60,100] but avoiding the nephrotoxicity associated with conventional amphotericin B may prove beneficial in delivering a longer duration of therapy. Delayed amphotericin B–based therapy (treatment ≥6 days after diagnosis) resulted in a two-fold increase in mortality (83% vs. 49%) and was an independent predictor of mortality in patients with hematologic malignancy and mucormycosis,[17] emphasizing the importance of aggressive management.

Most azoles, including fluconazole and voriconazole, have no meaningful activity against Zygomyecetes fungi. This point is critically important because voriconazole is an excellent antifungal against invasive aspergillosis, but has no clinical activity against mucormycosis. Multiple reports have suggested an increased risk for mucormycosis in patients receiving voriconazole prophylaxis.* One hypothesis posed to explain this association is that long-term exposure to voriconazole alters the nature of the fungal population in patients and provides a niche for new colonization by mucormycosis that are naturally resistant to voriconazole.[147] In addition, voriconazole may alter the virulence of mucormycosis. A study using murine and *Drosophila* models of mucormycosis found that exposure of Zygomycetes organisms to voriconazole by serial passage selectively enhanced their virulence.[66] Posaconazole, an approved orally available triazole, does possess potent activity against Zygomycetes.[140] However, in vitro time-kill studies have shown that although amphotericin B is rapidly fungicidal against Zygomycetes, with 95 percent killing in 6 hours and 99.9 percent killing at 24 hours, posaconazole has less than 70 percent killing at 6 hours and 99.9 percent killing only at 48 hours.[64] Therefore, in the critical early phase of therapy, the more rapidly fungicidal amphotericin B–based therapy is preferred. Another murine study found that posaconazole showed poor in vivo efficacy, which followed the very high mean fungicidal concentrations in contrast to the mean inhibitory concentrations.[121] Additional concerns regarding the effectiveness of posaconazole therapy for mucormycosis have been raised. It is unclear whether the posaconazole levels achieved in patients, particularly those with mucositis or diarrhea, are reliable and adequate to treat infections caused by mucormycosis.[62,63,70,141] Preclinical efficacy studies have shown poor activity of posaconazole despite the achievement of adequate serum levels (>5 μg/mL).[3] Furthermore, several investigators have found that posaconazole has virtually no activity against *R. oryzae*, one of the most common species causing infection.[26,45,117,136] Murine studies have failed to find evidence of an additive benefit of posaconazole when combined with polyene therapy.[45,117] In several more recent salvage therapy reports and studies, the overall success rate was 60 to 70 percent in patients with refractory disease.[107,144,125] Despite these encouraging results, its exact role in the treatment of mucormycosis remains unclear.

Echinocandins lack significant activity against Zygomycetes in vitro, and several cases of breakthrough mucormycosis have occurred in patients receiving echinocandin-based therapy.[59] However, *R. oryzae* expresses the gene encoding for the proteins of the 1,3-β-D-glucan synthase complex, and its enzyme activity is inhibited by caspofungin. Low dosage (0.5 mg/kg twice daily), but not higher doses of caspofungin, improved survival in a diabetic murine model of subacute disseminated zygomycosis.[43] When combined with amphotericin B lipid complex, caspofungin was more active than amphotericin B alone, or caspofungin alone, for the treatment of experimental, disseminated zygomycosis in diabetic mice.[133] Furthermore, Lamaris and colleagues[67] found that caspofungin uncovers β-glucan in the cell wall of *R. oryzae*. This effect of caspofungin is associated with enhanced activity of human neutrophils against the organism.[67] A clinical study of polyene-echinocandin combination therapy for mucormycoses found a benefit in patients who were predominantly non-neutropenic, and therefore this echinocandin-induced

*References 18, 47, 59, 81, 127, 147.

immunomodulatory activity of phagocytic cells may be particularly applicable to those with diabetes mellitus.[108] Whether the potentially beneficial effects of therapy with amphotericin B lipid complex plus an echinocandin are applicable to neutropenic patients or nonmyelosuppressed but immunosuppressed (e.g., corticosteroid-treated) hosts is not clear.

Hyperbaric oxygen therapy has been used as an adjunct to surgical and antifungal therapy for some patients in an attempt to limit the extent of gangrene and tissue necrosis.[24,34,53,105] The increased oxygen pressure achieved with hyperbaric therapy seems to improve the ability of neutrophils to kill organisms and inhibit fungal growth in vitro.[7] Although this regimen is apparently promising, the number of patients evaluated with this form of treatment is much too small to permit any firm conclusions on benefit. The role of other adjunctive therapies for mucormycosis has not been well studied. Granulocyte transfusions or cytokines that enhance phagocytic activity, such as interferon-γ and granulocyte-macrophage colony-stimulating factor, have been used occasionally to treat patients with mucormycosis.[1,39,129] Case reports have indicated favorable outcomes in patients treated with these adjunctive therapies,[1,129] but further studies are warranted before these therapies are recommended routinely.

Prognosis and Prevention

The disease site and host factors are key determinants of prognosis for mucormycosis. The reported mortality rate is highest for disseminated disease (100%), followed by gastrointestinal (85%), cerebral (79%), pulmonary (76%), and rhinocerebral (46%) disease.[116] Localized cutaneous disease is associated with a low mortality rate of 10 percent. Significant risk factors for mortality include disseminated disease and renal failure. Patients who undergo surgery as primary therapy and patients who receive antifungal therapy are significantly more likely to survive.[116] Among children, age younger than 1 year is associated with higher mortality.[162]

ENTOMOPHTHOROMYCOSIS

Pathogenesis and Pathology

Entomophthoromycosis presumably develops through inhalation of spores to cause sinus disease or cutaneous inoculation to cause cutaneous or subcutaneous infection. The exact mechanisms are unclear, however, and no specific animal model has been developed. The organisms are of extremely low virulence, as manifested by the rare occurrence of these infections despite the ubiquitous nature of the fungi. Although discrete clinical syndromes have been assigned to the two genera causing disease, this distinction is artificial, and the fact that either group could cause either form of entomophthoromycosis or even a syndrome more suggestive of mucormycosis should be recongnized.[112,123,153,155]

Histopathologic examination of affected tissues shows some similarities to that of mucormycosis. Areas of acute and chronic inflammation are found in association with broad hyphal elements that may or may not display septations. The hyphae are more visible with hematoxylin and eosin staining than with more specific fungal stains.[112] The tendency for vascular invasion typical of mucormycosis does not occur with entomophthoromycosis, however, and necrosis is uncommon. Instead, a Splendore-Hoeppli phenomenon, likely consisting of hyphae surrounded by eosinophilic material in a stellate pattern, occurs.[112] This feature is not pathognomonic of entomophthoromycosis, however, and has been seen in cases of mucormycosis.

Clinical Manifestations

Chronic Rhinofacial Entomophthoromycosis

Chronic rhinofacial entomophthoromycosis, also called *entomophthoromycosis conidiobolae* because most infections are caused by *Conidiobolus coronatus*, is an indolent subcutaneous infection involving the face.[42,88,92] Typically, bilateral intranasal swelling eventually progresses to invasion of the sinuses and soft tissue swelling of the face, unaccompanied by fever or pain. One infant developed orbital involvement from *C. coronatus* dacryocystitis.[76] Symptoms commonly persist for weeks or months, but deep tissue progression is unlikely to occur.

Chronic Subcutaneous Entomophthoromycosis

Chronic subcutaneous entomophthoromycosis, also known as *entomophthoromycosis basidiobolae*, is similar to chronic rhinofacial disease with the exception that the lesions usually are on the trunk or extremities. The etiologic agent is *Basidiobolus ranarum*. Painless subcutaneous nodules may progress to invade deeper soft tissues, and massive soft tissue swelling may develop. Facial infection similar to that of chronic rhinofacial entomophthoromycosis also may occur.[30] *Conidiobolus incongruus* has caused orbitofacial disease in a child residing in the Middle East.[2] With rare exceptions, most cases of subcutaneous entomophthoromycosis are slowly progressive.[51,112]

Gastrointestinal Basidiobolomycosis

Gastrointestinal basidiobolomycosis is an extremely rare condition resulting from *B. ranarum* infection of the gastrointestinal tract. A cluster of cases was identified in Arizona in the late 1990s, suggesting a possible emerging infection in the region. In a case-control study including seven adult patients in Arizona, infected patients tended to be more likely to use ranitidine and to have resided in Arizona for a longer time in contrast to controls.[78] Clinical features included abdominal pain, leukocytosis, and eosinophilia. Combined surgical resection and itraconazole appeared to be effective treatment.

Diagnosis

Entomophthoromycosis often can be diagnosed presumptively on the basis of clinical presentation and geographic origin of the patient, but usually biopsy is

required.[112] More recent work on serodiagnosis by immunodiffusion has had promising results.[48,54] Onchocerciasis, filariasis, and Burkitt lymphoma sometimes are in the differential diagnosis.[51,112]

Treatment

Evaluating therapy for this group of diseases is difficult because of occasional reports of spontaneous resolution. Many agents have been tried with variable success. Taylor and colleagues[137] treated a young man with rhinofacial disease with amphotericin B, corticosteroids, miconazole, and multiple surgical procedures before noting resolution some months after any therapy had been given. Susceptibility testing of the isolate on that patient showed minimal inhibitory effects of amphotericin B and no benefit of adding flucytosine or rifampin; miconazole, ketoconazole, and potassium iodide did not have impressive in vitro activity. Other investigators recommend potassium iodide therapy, with trimethoprim-sulfamethoxazole as an alternative.[110]

Other anecdotal reports of efficacy of trimethoprim-sulfamethoxazole, ketoconazole, and itraconazole raise hopes for effective therapy but must be tempered by the fact that only small numbers of patients have been treated.[42,78,137] Currently, no antifungal is the preferred treatment for this condition, although some type of medical therapy seems indicated for all cases. Data regarding the activity of posaconazole against this group of fungi are unavailable. The role of surgery is less for this group of disorders than for mucormycosis, but patients with well-circumscribed areas, such as nodular lesions, may benefit from surgical excision. Despite surgery, recurrence of disease after surgery commonly occurs in such patients.[137]

Prognosis and Prevention

Mortality caused by entomophthoromycoses is unlikely to occur, but morbidity and disfigurement are common. The efficacy of medical and surgical therapy is unclear, but all patients should likely receive attempts at treatment because the natural history of the disease is one of slow progression. Specific means for preventing disease are unavailable because so little is known about factors predisposing individuals to these chronic entomophthoromycotic syndromes.

CHAPTER 206

Fusariosis and Scedosporiosis

Damian J. Krysan • Melanie Wellington • William J. Steinbach

Fusarium and *Scedosporium* are species of molds that cause hyalohyphomycosis. Hyalohyphomycoses, although not as common as invasive aspergillosis or mucormycosis, are invasive fungal infections caused by nondematiaceous molds that lack cell wall melanin and thus are nonpigmented, in contrast to phaeohyphomycoses, which are fungal infections caused by pigmented molds. In profoundly immunocompromised patients, fusariosis and scedosporiosis are increasing in prevalence and are associated with high mortality.

INFECTIONS CAUSED BY *FUSARIUM* SPECIES

Microbiology and Pathogenesis of Infection

Molds of the *Fusarium* genus are saprophytic environmental fungi that are well recognized as plant pathogens and, increasingly, as the cause of human infections.[17,47,50] *Fusarium* species are among the organisms that cause hyalohyphomycosis by virtue of their characteristic tissue form consisting of hyaline-like branching or nonbranching hyphal elements.[17] The most common clinical *Fusarium* isolates include *Fusarium solani* (50%), *Fusarium oxysporum* (20%), *Fusarium moniliforme* (10%), and *Fusarium verticillioidis* (10%).[47,50] In immunocompetent patients, *Fusarium* is the most common cause of fungal keratitis; *F. oxysporum* is the predominant organism.[17,47,50,64] Keratitis can progress to endophthalmitis, but this is more common in immunocompromised patients.[50] In addition, *Fusarium* is an important cause of onychomycosis.[48] Invasive fusarial disease can develop in immunocompetent patients who have had tissue breakdown due to trauma or burns[49] and in patients who have indwelling catheters, such as for vascular access, hemodialysis, or peritoneal dialysis.[20] Among immunocompromised patients, *Fusarium* is an emerging cause of infection[51]; according to data published before 2011, *Fusarium* was the second most common filamentous fungal pathogen in hematopoietic stem cell transplant recipients after *Aspergillus* species,[8,50] causing disseminated disease characterized by pneumonia, fungemia, and cutaneous manifestations. Data from the Transplant-Associated Infection Surveillance Network (TRANSNET) indicate that *Fusarium* species are now the third most common cause of mold infections in transplant recipients after *Aspergillus* and Mucorales.[54]

The portal of entry for most cases of disseminated *Fusarium* infections is the respiratory tract, but access to the patient may also be gained through vascular catheters.[1,8,19,47,51] *Fusarium* species have a propensity for vascular invasion, resulting in thrombosis and tissue necrosis, as well as for dissemination to extrapulmonary tissues.[49] One of the characteristics of *Fusarium* infections compared with other molds such as *Aspergillus* is that there is a high rate of fungemia. Many isolates of *Fusarium* species are capable of producing a yeast-like synanamorph when the microconidia enlarge; then, instead of germinating to form hyphae, these give rise directly to unicellular propagules, called adventitious sporulation (Fig. 206-1). This leads to a rapid dissemination and could explain the higher rate of positive blood cultures compared with other molds, such as *Aspergillus* species.[8] Another explanation for the high rate of positive blood cultures is the potential ability of *Fusarium* organisms to sporulate by forming phialides and phialoconidia within the human body.[58]

Risk Factors and Clinical Syndromes

One of the most common fusarial infections of immunocompetent patients is keratitis.[17,50,64] An outbreak of

fusarial keratitis occurred in 2006 in contact lens wearers[14,30] in association with a specific contact lens solution (ReNu with MoistureLoc) and resolved after the product was voluntarily removed from the market. Onychomycosis is a second common manifestation of fusarial infection in immunocompetent hosts and typically results from environmental contamination of the great toenail, presenting as proximal subungual onychomycosis.[61]

In immunocompromised patients, invasive fusariosis shares many characteristics with invasive aspergillosis, including the risk factors of neutropenia and corticosteroid exposure, which results in a similar bimodal distribution (before and after engraftment) in hematopoietic stem cell transplant recipients.[8,50,51] Among allogeneic hematopoietic stem cell transplant recipients with fusariosis, other risk factors identified in multivariate models include severe graft-versus-host disease and an underlying diagnosis of multiple myeloma.[42,50,51]

The incidence of fusariosis appears to be affected by both geography and season. A multicenter retrospective study found that fusariosis occurred more frequently in the summer and autumn months than in the winter and spring months. The infections were more likely to occur during the rainy season, which was thought to be due to the dispersal of the soil-borne fungi by the rain and wind.[47] More recently, reports have suggested that this organism may also be acquired through hospital water supplies.[1]

Invasive fusariosis in hematopoietic stem cell transplant recipients most frequently is manifested as invasive pulmonary disease, with dissemination to the extrapulmonary organs in as many as 70 percent of cases.[42] Widespread skin lesions occur in approximately 70 percent of cases (Fig. 206-2), in sharp contrast to invasive aspergillus, which has skin manifestations in less than 5 percent of cases.[49] Cutaneous lesions may take several forms, including painful, discrete, erythematous nodules; raised keratotic masses; and violaceous papules and nodules that break down to form black necrotic centers.[49] Although these skin lesions are typically larger, more erythematous, and more painful than those caused by *Aspergillus* species, the appearance is not specific for fusariosis. Other filamentous fungi, such as *Acremonium* species, can cause similar skin lesions, in which the characteristic yeast-like structures are noted on histopathologic examination. However, culture of skin lesions was the most important basis for the diagnosis of fusariosis in a series of immunocompromised patients[49]; therefore, in this population of patients, biopsy specimens of all skin lesions should be taken and evaluated by both culture and histology.

Localized cutaneous infections can also occur in immunocompromised patients; the most common manifestations are onychomycoses and cellulitis. Because localized infections may progress to involve cellulitis and may lead to disseminated infection, *Fusarium* isolated in nail cultures should not be dismissed as a contaminant in an immunocompromised patient.[5,8,47]

Diagnosis and Therapy

The clinical presentation of fusariosis has no features that reliably distinguish it from other invasive fungal infections. In addition, no specific diagnostic methods exist for fusariosis except for histopathology and the microbiologic examination of blood, sputum, and biopsy tissues. Major clues to *Fusarium* infections include blood cultures positive for mold and the presence of the characteristic skin lesions. In contrast to aspergillosis,

Fusarium species are isolated from the bloodstream in approximately 50 percent of patients.[49] Non–culture-based methods have been developed for the diagnosis of invasive fungal disease by the detection of galactomannan and (1→3)-β-D-glucan in the serum.[32,52] Like most other fungi, *Fusarium* species are generally positive in the (1→3)-β-D-glucan assay.[52] Some *Fusarium* species have been reported to contain galactomannan in vitro. For example, a report described a patient who had a positive galactomannan test result and was subsequently diagnosed with culture-confirmed fusariosis; additional in vitro testing confirmed that *Fusarium* isolates were positive for galactomannan.[44]

In general, *Fusarium* species are relatively resistant to most clinically used antifungal agents on the basis of in vitro studies. Among currently available agents, voriconazole and amphotericin B are the most active.[50] Keratitis is typically treated with topical natamycin, although studies of topical voriconazole indicate that it may be an alternative.[4] Echinocandins have very little activity in vitro against *Fusarium*.[63] Compared with other fungi, the minimum inhibitory concentrations (MICs) for amphotericin B–based agents are high (0.5 to 8 μg/mL); accordingly, animal studies indicate minimal therapeutic responses to lower doses of amphotericin B formulations.[22,36]

Reports have indicated that voriconazole and posaconazole have good in vitro and in vivo activity against experimental *Fusarium* infections.[22,36] Currently, both voriconazole and posaconazole are licensed by the Food and Drug Administration for salvage treatment of fusariosis.[45] A retrospective analysis of 73 cases of fusariosis treated with voriconazole suggested that voriconazole has efficacy that is comparable to the historical response rate reported for patients treated with amphotericin B.[35] Combination drug studies have also been reported, with in vitro synergy demonstrated with a combination of amphotericin B and either 5-flucytosine or rifampin.[3] Similarly, the combination of amphotericin B and caspofungin has been shown to yield synergistic or additive interactions with no antagonism observed in vitro.[34] In addition, there have been a number of case reports of the successful use of combinations of antifungals in the treatment of patients.[34]

As an approach to the treatment of fusariosis, high-dose intravenous amphotericin B lipid formulation has been generally regarded as a first-line option.[45] However, the case series of patients treated with voriconazole strongly support the notion that it is at least as effective as amphotericin B, and given its better tolerability, voriconazole may be a superior choice.[35]

Neutropenia is a prime risk factor for disseminated infection, and without the recovery of neutrophils, *Fusarium* infection is fatal.[46,51] A large clinical review, which included 43 cases of invasive fusariosis at one center and 54 cases from the literature, reported a response to therapy of 30 percent and 48 percent, respectively. Cure was observed only in those patients showing resolution of myelosuppression.[8] Attention to immune reconstitution is critical; granulocyte transfusions and the administration of colony-stimulating growth factors should be considered in all patients who are persistently neutropenic. Another review of fusariosis that was diagnosed among hematopoietic stem cell transplant recipients in nine centers in the United States and Brazil found that the survival after diagnosis was only 13 percent, with a median duration of 13 days.[51]

In summary, invasive fusariosis can be extremely difficult to diagnose and to treat. In the immunocompromised patient, the clinical presentation often mimics invasive aspergillosis, but it has some unique features. Because standard doses of amphotericin B do not appear to be consistently effective, voriconazole has emerged as an attractive option for the treatment of fusariosis. Similar to invasive aspergillosis, the attention to the recovery of neutrophils is paramount, and control of the underlying disease is essential to a favorable outcome. Surgery may decrease the fungal burden and may provide time for the recovery of immune function.[38] Because of the ability of *Fusarium* organisms to attach to and to degrade plastics, removal of infected catheters and prosthetic devices is, as always, strongly recommended.

INFECTIONS CAUSED BY *SCEDOSPORIUM* SPECIES

Microbiology and Pathogenesis

Scedosporium is a taxonomically complex genus, of which the two most medically significant species are *Scedosporium prolificans* and *Scedosporium apiospermum*.[15,31] This genus has morphologic characteristics of both hyaline and dematiaceous molds.[15] *S. apiospermum* is the anamorph, or asexual stage, of *Pseudallescheria boydii*, a species that has undergone several taxonomic name changes. *S. prolificans* is a relatively new species of mold that was first described in 1984 after being isolated from a deep, subcutaneous lesion in the right foot of a 6-year-old boy[15]; it was initially named *Scedosporium inflatum* and later renamed.[12,26,40] More recently, human infections involving a third species, *Scedosporium aurantiacum*, have been described in a large population-based survey of *Scedosporium* infections in Australia.[25]

Scedosporium species are ubiquitous fungi recovered worldwide from polluted water, soil, and poultry and cattle manure.* *S. apiospermum* appears to be more prevalent in temperate climates compared with tropical regions.[15] *S. prolificans* has mainly been isolated in the Iberian peninsula, Australia, southern United States, and California.[15] In the United States, for example, *S. prolificans*–associated bone and joint infections appear to be more common in those areas.[28] *S. prolificans* was found to be the most abundant pathogen in plant soils in hospitals.[59]

Like other pathogenic molds, *Scedosporium* species cause disease in both immunocompetent and immunocompromised people, with localized infections most common in immunocompetent patients and disseminated infections almost exclusively limited to immunocompromised patients.[15] The first disseminated case of *S. prolificans* was reported in 1991,[41] and since that time,

*References 15, 23, 25, 26, 31, 40, 60, 65.

FIGURE 206-3 ■ Pathology specimen from a patient with lumbar vertebral *Scedosporium apiospermum* infection. (See companion Expert Consult website for color version.) (Courtesy Wiley Schell, Duke University.)

Scedosporium species have emerged as the fourth most common cause of invasive mold infections in transplant recipients after *Aspergillus*, Mucorales, and *Fusarium*.[54] The mortality rates associated with disseminated *Scedosporium* infections in immunocompromised patients are extremely high, ranging between 58 percent and 100 percent in reported case series.*

The respiratory tract appears to be the portal of entry for disseminated infection in most cases, although the organism can also invade through ulcerative lesions in the gastrointestinal tract, through surgical wounds, or by inoculation from trauma.[15] In localized infection, the most common mechanism seems to be direct inoculation of wounds by organisms in the environment.[15,40] Germination into hyphae can result in hematogenous dissemination to other organs, particularly the kidneys, lungs, and brain. In the tissue, both the *Pseudallescheria* and *Scedosporium* species form slender, septate hyphae with parallel cell walls that cannot reliably be distinguished from other molds, such as *Aspergillus* or *Fusarium* species, unless conidia are present.[15,23,36]

Risk Factors and Clinical Syndromes

In immunocompetent patients, *P. boydii* is an important cause of mycetoma, a clinical syndrome characterized by infection of soft and connective tissue, joints, and bone by soil-borne fungi.[43] *P. boydii* has been estimated to cause approximately 10 percent of mycetoma worldwide.[15] Case series in the United States and Brazil found that *P. boydii* is the most common cause of fungal mycetoma in these regions.[21,57] Mycetoma displays a characteristic triad of symptoms[15]: tumefaction or edematous tissue; draining sinus track formation; and presence of "grains" (balls of fungal hyphae) in pus. Although localized nonmycetomatous infections involving a wide range of anatomic sites in immunocompetent patients have been reported (Fig. 206-3), they are uncommon.[15]

An important clinical manifestation of *P. boydii* disease in immunocompetent patients is its association with sinopulmonary and central nervous system infection of victims of near-drowning incidents in polluted waters.[10,15] The syndrome affects previously healthy individuals and generally is manifested within days to weeks of the incident, although presentation has been delayed up to nearly 5 months.[15] Dissemination from the lungs to a range of anatomic sites has been reported, but the syndrome is most commonly characterized by the formation of brain abscesses.[10,18] Although *P. boydii* is the most common mold associated with near-drowning–related infections, *Aspergillus* can also cause a similar syndrome[33]; in contrast, *S. prolificans* has not been associated with near-drowning.[15] Unfortunately, near-drowning–associated *P. boydii* infections carry a very poor prognosis with mortality greater than 70 percent.[15]

Consistent with the respiratory tract's being the most common portal of entry, *Scedosporium* species also appear to be transient colonizers of the sinopulmonary tract. A model for the host-pathogen interaction in pulmonary scedosporiosis was proposed by Cortez and associates,[15] in which transient colonization occurs that in the setting of a normal respiratory tract is clinically insignificant. If the pulmonary tract has been altered by the presence of a fixed cavity, damage due to tuberculosis, or cystic fibrosis, persistent colonization can result.[7] The first report of this occurrence was in 1955 and involved a patient with a previous pyogenic abscess that was subsequently colonized by *P. boydii*.[16] As with *Aspergillus*, persistent colonization of dysfunctional airways with *Scedosporium* species could trigger a syndrome similar to allergic bronchopulmonary aspergillosis; however, only three such cases have been reported in the literature.[15] *S. apiospermum* appears to be a relatively common component of respiratory cultures isolated from patients with cystic fibrosis. Although a case report has described the possible cerebral dissemination of *S. apiospermum* in a patient with cystic fibrosis,[56] the clinical significance of this colonization is not entirely clear.[57] However, the presence of molds such as *Scedosporium* species may be more relevant as more cystic fibrosis patients undergo lung transplantation, as illustrated by a case report describing the death of such a patient from disseminated *S. apiospermum* infection after double-lung transplantation.[62] This report emphasizes the notion that colonization of the airway can lead to dissemination when the immune status of the patient is altered.

The role of *Scedosporium* species in mold infections of immunocompromised patients has become more apparent as an increasing number of case series and large multicenter surveillance data have become available.* *Scedosporium* is among the four most commonly isolated molds associated with invasive disease in immunocompromised patients. The rate of disseminated disease in one study was 69 percent for hematopoietic stem cell transplant patients and 53 percent for solid-organ transplant patients.[27] Risk factors and clinical manifestations parallel those caused by other filamentous molds, such as *Aspergillus* and *Fusarium* species.† Prognosis is similarly

*References 6, 27, 37, 39, 53, 54, 55.

*References 6, 15, 25, 27, 28, 37, 53, 54, 65.
†References 6, 15, 25, 27, 28, 37, 39, 53, 54, 55, 65.

poor; for example, a large multicenter case series of infections involving transplant patients found that the overall mortality was 58 percent.[27]

In general, although *Scedosporium* infection is often clinically and radiographically indistinguishable from other filamentous fungi infections in neutropenic patients, several unique, salient features are present that reflect a large amount of fungal replication in vivo. These include a high incidence of positive blood cultures, characteristic although not pathognomonic erythematous cutaneous lesions, frequent hematogenous spread to the central nervous system, and a high incidence of visual complaints because of endophthalmitis.*

Diagnosis and Therapy

Histologic findings are insufficient to distinguish *Scedosporium* from other filamentous fungi, such as the *Aspergillus* species. However, scedosporiosis is frequently characterized by a high frequency of positive blood cultures. In fact, from 1990 to 1999, *S. prolificans* was the most common filamentous fungus isolated from blood culture at one hospital in Spain.[28] In another report, 12 of 16 patients with *Scedosporium* infections had growth in blood culture, 4 of 16 had growth in respiratory tract specimens, and 3 of 16 had growth in skin biopsy specimens.[6] No specific studies evaluating β-glucan or galactomannan assays in the setting of proven *Scedosporium* infections have been reported, so the utility of these methods in detecting this species of mold is unclear.

Scedosporium species have low in vitro susceptibility to currently available antifungal drugs, a fact that certainly contributes to the dismal outcomes associated with these infections. The excellent review by Cortez and associates presented a large set of susceptibility data from a variety of isolates.[15] In general, *S. apiospermum* appears more susceptible than *S. prolificans*. The agent most active[15] against *S. apiospermum* is voriconazole (median MIC_{50} of 0.25 μg/mL), whereas amphotericin B has poor activity with an MIC_{50} of 4 μg/mL.[15] As with other molds, a number of studies have examined the activity of combinations of antifungal drugs, but none yielded particularly encouraging results.[35]

The in vitro activity of a number of azoles currently under development (albaconazole [UR-9825], isavuconazole, and ravuconazole) against *Scedosporium* species has been reported.[12,24] Of these agents, albaconazole is the most active, with geometric mean MICs toward *S. prolificans* and *S. apiospermum* of 0.35 μg/mL and 1.0 μg/mL, respectively.[12] Encouragingly, albaconazole has been shown to have efficacy superior to that of amphotericin B in a rabbit model of disseminated *S. prolificans* infection.[11]

A case series describing the treatment of scedosporiosis with voriconazole collated from the global voriconazole clinical trials database suggested that voriconazole has promising activity against both *S. apiospermum* and *S. prolificans*.[62] In this uncontrolled, observational series, an overall response to therapy rate was 57 percent and overall mortality was 40 percent. Although it is difficult to make conclusions from this study, these rates are much better than those reported in previous case series.*

Because of the resistance of this fungus to antifungal drugs, immune function and surgical intervention play critical roles. The prognosis is particularly grim for patients with persistent neutropenia. For example, a case series of 16 patients with *S. prolificans* infections revealed that all patients who failed to recover neutrophils died.[6] Anecdotal reports of success have been noted with the adjunctive use of granulocyte colony-stimulating factor and interferon-γ.[9,29] These immunomodulation-based approaches are similar to those applied to other mold infections, but to date, none has progressed to the state at which it can be routinely recommended.[2] Surgical resection, combined with systemic antifungal therapy, should be pursued when feasible and was reported to be successful for a near-drowning victim.[13]

In summary, *Scedosporium* infections are difficult to treat and frequently occur in the immunocompromised host. The standard of care for localized infections in an immunocompetent host is surgical excision whenever possible, particularly because these organisms are highly resistant to antifungal therapy. In the immunocompromised host, in whom disseminated disease renders this approach useless, *Scedosporium* infections are generally rapidly fatal unless immune reconstitution occurs. Voriconazole appears to be the most active antifungal drug in this setting and should be considered the agent of choice.

CHAPTER 207

Miscellaneous Mycoses

William J. Steinbach

The landscape of medical mycology is changing. Fungi that were once innocent or only contaminants are now emerging to lead to lethal disseminated disease in immunocompromised patients. Although we are only beginning to learn about the full implications of some of these fungi, there is also the realization that nearly all of the therapeutic evaluations in these emerging pathogens are in vitro analyses with limited case report clinical experience. Every miscellaneous mycosis and fungal opportunist cannot be listed, and the field of taxonomy is dynamic, coupled with continued reports of previously nonpathogenic fungi now infecting severely immunocompromised patients. This chapter will highlight the most relevant miscellaneous fungi causing disease. Often these diseases can be classified as infection through trauma or inoculation, such as keratitis, myectoma, or soft tissue infection or as more invasive disease such as sinusitis, peritonitis, or disseminated infection.

YEASTS

Malassezia Species

Fourteen *Malassezia* spp. have been isolated from normal and diseased human and animal skin, with *Malassezia furfur* the most common species. Most microbiologists identify *M. furfur* as the "spaghetti and meatball"–appearing yeast that causes the prototypical skin disease tinea versicolor (also known as pityriasis versicolor), characterized by hypopigmented or hyperpigmented plaques covered in scales and generally distributed over the back, chest, and neck. Evidence also suggests that seborrheic dermatitis results from a nonspecific immune response to *Malassezia* yeasts, and dandruff is linked to this yeast as well, while research continues as to the role of this yeast in atopic eczema and psoriasis. However, this yeast is also responsible for intravascular catheter-related sepsis in immunocompromised patients, particularly neonates, receiving parenteral fat emulsions for nutrition.

M. furfur is a lipophilic yeast that lacks the ability to synthesize long-chain fatty acids and requires an exogenous supply of lipids for growth, growing in culture only if C12 through C24 fatty acids are added to the medium. The great majority of the lipids in parenteral intralipid formulations are C16 and C18 fatty acids, chiefly linoleic acid and oleic acid.[41] This absolute requirement for long fatty acid chains leads to specific procedures required for isolation, conservation, and identification. Whereas *M. furfur* is obligatory lipophilic, another major species, *Malassezia pachydermatis*, does not require lipids for growth.

The first invasive disease reported with *Malassezia* spp. was a patient with chronic renal failure treated with peritoneal dialysis who had repeated episodes of "sterile" peritonitis, with high levels of cholesterol and triglyceride found in the peritoneal fluid after meals, thought to have originated from the small intestinal lymphatics. The yeast did not grow in culture until the agar was overlaid with olive oil.[70] Neonatal systemic *Malassezia* disease was first reported in 1981 in a 740-g premature infant on long-term intralipid therapy.[49]

Lipophilic *Malassezia* spp. infections (e.g., with *M. furfur*) can be divided in two major groups: the first comprising children and adults with various forms of immunosuppression, and the second involving infants on parenteral nutrition. The majority of published case reports and mini-epidemics have involved infants, children, and adults with profound immunosuppression, serious concurrent health problems, and the infusion of

total parenteral nutrition with lipid supplementation through central vascular catheters.[20] There have been numerous outbreaks in neonates involving *M. furfur*; and fewer outbreaks involving *M. pachydermatis;* it is more commonly involved in otitis externa of dogs, and one outbreak was associated with the colonized dogs of health care workers.[5] A review of 55 neonates infected with *Malassezia* spp. found that prematurity was the most common underlying condition, followed by short-gut syndrome, but that all infected infants were receiving intralipid supplementation.[34]

Adults are nearly universally colonized with *Malassezia* spp. A study of the prevalence of *M. furfur* skin colonization of infants hospitalized in the intensive care unit found that of the 361 infants studied over 1 year, 133 (36.8%) had at least one positive culture for *M. furfur.* Colonized infants in contrast to noncolonized infants, had younger mean gestational age, lower mean birth weight, a longer stay in the hospital, and more mean days use of an incubator, lamb wool, paper tape, and Op-Site tape, suggesting that hospitalization in an intensive care unit often leads to *M. furfur* colonization.[47]

The use of intravenous fat emulsions appears to alter the microenvironment of the catheter and allowed colonization and subsequent infection. Dissemination of the organism appears to be limited to the lungs, which at autopsy show lipid deposits in the arterial walls. Because of the serious underlying disease(s) of patients with *M. furfur* catheter sepsis, it is difficult to determine the exact role of the organism in the overall status of the patients.[33] In an effort to determine if intralipid contamination was the source of these outbreaks, an experimental study found that six blood culture isolates of *M. furfur* from infected patients grow well in both 10 and 20 percent parenteral fat emulsions at 35° C (95° F) for 6 days. Room temperature growth was much slower, but there was no loss of viability. The authors concluded that intralipid solution provided more optimal supplementation than vegetable oils.[46]

A review of 16 infants infected with *M. furfur* revealed most presented with classic signs of sepsis, including apnea and bradycardia, and 9 had radiographic film evidence of interstitial pneumonitis to accompany worsening pulmonary status. Abnormal laboratory tests included leukocytosis, elevated neutrophil band counts, and thrombocytopenia. Blood cultures were most commonly positive from the central catheter, with few peripheral (noncatheter) blood cultures positive and few organisms found on those positive cultures.[33]

Clinicians must maintain a high index of suspicion of *M. furfur* catheter sepsis in the appropriate clinical setting, and laboratory investigators must be prepared to provide appropriate diagnostic methods.[33] Culture of biologic fluids and biopsy specimens in selective media, as well as an increased incubation time (10 to 15 days), would increase the rate of isolation of lipophilic *Malassezia* spp. The blood of infants receiving lipid emulsions probably contains sufficient lipid to support initial growth of the organism, but would not be sufficient for routine identification. On subculturing, a few drops of olive oil placed on the agar surface will help in isolation.[33]

The diagnosis should not be overlooked when evaluating symptomatic, low-birth-weight, premature infants receiving total parenteral nutrition with lipid supplementation, because simple removal of the catheter after the identification of the causative agent can lead to clinical improvement. In fungemia, removal of the catheter is the key to therapy and appears to be the only therapy necessary for *M. furfur* catheter sepsis. Most treatments in the literature focus on topical or systemic agents for the minor skin infection and not on disseminated disease. In vitro antifungal susceptibility testing against 95 *Malassezia* spp. isolates (including 74 *M. furfur* strains) revealed excellent antifungal activity with itraconazole, voriconazole, and ketoconazole, and limited activity with fluconazole.[37] The poor response to amphotericin B is supported by the in vitro high minimum inhibitory concentration (MIC) values of this agent.[33] Catheter removal or discontinuance of the fat emulsion therapy is required, and antifungal therapy without either of these two steps has not been shown to be efficacious.

Trichosporon *Species*

Fungemia caused by *Trichosporon* spp. is increasing in patients with hematologic malignancies and neutropenia and has been reported as the second most common yeast infection in cancer patients after *Candida* spp.[29] One study showed 10 percent of all fungemias at one institution were caused by *Trichosporon* spp.[29] *Trichosporon* spp. are able to colonize and proliferate in various parts of the human body, including the gastrointestinal system, respiratory tract, skin, and vagina. More than 10 percent of people have been shown to be colonized by *Trichosporon* spp. on their normal perigenital skin (i.e., scrotal, perianal, and inguinal sites of the body).[7] The opportunistic *Trichosporon* spp. are therefore part of the cutaneous fungal microbiota in humans, and this cutaneous position may be one of the routes through which deep-seated trichosporonosis is acquired. *Trichosporon* spp. may cause deep-seated, mucosa-associated, or superficial, infections, with invasive trichosporonosis documented in patients with hematologic malignancies and other immunosuppressive states, whereas superficial infections and allergic pneumonia are found predominantly in immunocompetent hosts.[7]

The taxonomy of *Trichosporon* has been revised several times. The most frequently reported species are *Trichosporon asahii* (formerly *Trichosporon beigelii* and *Trichosporon cutaneum*), *Trichosporon pullulans*, and *Trichosporon capitatum* (formerly *Blastoschizomyces capitatus*).[38] Culture identification of *Trichosporon* spp. may be difficult; it is often morphologically confused with *Candida* spp., which is worrisome because *Trichosporon* organisms have decreased susceptibility to amphotericin B.

The clinical presentation of superficial *Trichosporon* infection in humans is often benign superficial lesions of hair, called white piedra, characterized by the presence of irregular nodules on the affected hair. These nodules are loosely attached to the hair shaft, have a soft texture, and may be white or light brown. White piedra is a disease affecting children and adults from areas with tropical and temperate climates, and most cases have been reported

in children and young adults, particularly females who frequently use headbands.[7]

The first case of invasive trichosporonosis was described in 1970.[72] Clinically, the genus often causes catheter-related fungemia, but there are reports of endocarditis,[6] peritonitis,[31] meningitis,[2] and pneumonitis.[58] Infections with invasive *Trichosporon* spp. usually are associated with central venous catheters, bladder catheters, and peritoneal catheter-related devices. The ability to form biofilms on implanted devices aids in the development of invasive trichosporonosis, because it can promote escape from antifungals and host immune responses. Similar to biofilms of *Candida* spp., *T. asahii* cells are able to rapidly adhere to polystyrene after a 30-minute incubation.[10]

A multicenter retrospective Italian study was conducted to characterize cases of proved or probable invasive trichosporonosis diagnosed over the past 20 years in patients with hematologic diseases. Of 17 cases classified as *Trichosporon* spp. infections, acute myeloid leukemia accounted for 65.4 percent of the cases, leading to an incidence of 0.4 percent of *Trichosporon* spp. in patients with acute leukemia, including 76.9 percent of cases with a positive blood culture. Pulmonary involvement was documented in 26.9 percent of cases, and death was reported for 64.7 percent of *Trichosporon* spp. infections. A literature review on 287 trichosporonosis published cases with any underlying disease revealed *Trichosporon* spp. infections are seen with similar frequencies on all continents. The majority of published *Trichosporon* spp. infections occurred in patients with hematologic diseases (62.8%), with more than half having acute leukemia (68% of all patients with *Trichosporon* spp.). Crude mortality rates were 77 percent for *Trichosporon* spp.[23] One study of 39 *Trichosporon* clinical isolates showed high MICs for amphotericin B, with fluconazole and itraconazole relatively lower. Posaconazole and voriconazole appeared to be more active than amphotericin B or fluconazole and have activity similar to that of itraconazole. Fungicidal effects were also possible with the triazoles.[42] An in vitro study with 8 *Trichosporon* spp. isolates showed voriconazole was most effective and slightly more active than itraconazole, and amphotericin B, and fluconazole.[65] Another study demonstrated that voriconazole showed excellent activity, superior to that of amphotericin B, itraconazole, and fluconazole.[15] In vitro activity against several *Trichosporon* spp. showed voriconazole to be far superior to amphotericin B, fluconazole, and itraconazole. Notably, *T. pullulans* was generally more resistant to antifungals, including total resistance to amphotericin B and fluconazole.[36] In vitro studies against *T. beigelii* showed the echinocandins caspofungin and anidulafungin to have no activity.[14] This inactivity was validated in further studies with micafungin[63] and anidulafungin.[66] Invasive *T. beigelii* infection has also developed in a bone marrow transplant patient who was receiving caspofungin prophylaxis against *Aspergillus* infection.[24]

Trichosporon spp. have limited susceptibility to amphotericin B, and earlier clinical studies and animal models showed azoles were effective therapy[3] and azoles plus polyenes were potentially additive.[4] In one study, 5/12 reported cases occurred while the patient was on itraconazole prophylaxis and 11/12 patients died despite amphotericin B therapy.[29] The mortality of hematogenous trichosporonisis was higher than that of candidiasis in that study, confirmed by a review of the published literature in the last 20 years showing *Trichosporon* spp. mortality of 64 to 80 percent[29] and central venous catheters the most frequent risk factor for fungemia.

Girmenia and colleagues[23] reported the clinical outcomes for 55 patients with hematologic diseases and disseminated trichosporonosis who were treated with amphotericin B. A clinical response to amphotericin B was documented in only 13/55 (24%) of the patients evaluated. Echinocandins alone have little to no activity against *Trichosporon* spp. and are not recommended for trichosporonosis treatment. Indeed, breakthrough trichosporonosis in immunocompromised patients after administration of amphotericin B and echinocandins, and more rarely after the use of triazoles, has been extensively reported.[7]

Rhodotorula mucilaginosa

Rhodotorula mucilaginosa (formerly *Rhodotorula rubra*) is considered ubiquitous because of its worldwide distribution in terrestrial, freshwater, and marine habitats, and to its ability to colonize a large variety of substrates. *Rhodotorula* is naturally found in soil, water, and plants and is a constituent of the normal human respiratory, gastrointestinal, and genitourinary flora.[56] Previously this organism was considered only a harmless colonizer when isolated from healthy individuals, but it is now reported in immunocompromised patients, causing fungemia, endocarditis, meningitis, and peritonitis.[28] This is also the fungus that is chiefly responsible for the pink ring left in toilet bowls.

In vitro testing of 35 clinical samples of *Rhodotorula* spp. showed low MICs against all agents tested, including amphotericin B, ketoconazole, fluorocytosine, and itraconazole. The azoles were generally less effective than amphotericin B, and fluconazole showed an MIC greater than 32 μg/mL against all isolates.[21] In vitro amphotericin B is slightly superior to voriconazole and itraconazole, with general fluconazole resistance.[15]

In review of all 43 reported cases from 1960 to 2000, the most common risk factor was central venous catheter insertion. It appears that the yeast is already an inhabitant of the skin and mucosa and is introduced into the bloodstream after a disruption of normal anatomic barriers. In contrast to *Trichosporon*, mortality with *Rhodotorula* is uncommon. In a review, 10/36 survivors of infection were not treated with antifungals and appeared to respond to removal of the infected catheter.[56] This yeast has a strong affinity for plastic,[1] and almost all published cases involve long-term catheter placement. One single series reported 23 cases of fungemia; only 2 of the patients were neutropenic, and outcome was favorable in all using various treatment strategies of line removal alone, removal with amphotericin B, or antifungal therapy alone.[28]

A review of 29 cases of *Rhodotorula* fungemia in Spain found that the most common underlying hematologic disorder was acute leukemia (65.5%). *R. mucilaginosa* was the species found more frequently (79.3%), and the

most common predisposing factors were the presence of central venous catheter (100%) and neutropenia (62.1%). Most patients (81.5%) were treated with amphotericin B, and the overall mortality was higher (13.8%) than that described in patients with nonhematologic disease (5.8% in solid-organ neoplasms and 9% in acquired immunodeficiency syndrome [AIDS] or other chronic diseases). Patients with acute leukemia had a higher mortality rate (15.7%) than patients with non-Hodgkin lymphoma (0%).[22]

A review of 25 Brazilian cases of *Rhodotorula* spp. isolated from blood cultures found that the majority of patients (88%) had a central venous catheter and 40 percent were bone marrow transplant recipients; 80 percent of cases were classified as a bloodstream infection. Amphotericin B was the most common antifungal used; the catheter was removed in 89.5 percent of the patients, and death occurred in 4 patients (17.4%). All strains were identified as *R. mucilaginosa* and amphotericin B demonstrated good in vitro activity, and fluconazole had no activity.[8] Because of *Rhodotorula* spp. resistance to fluconazole and echinocandin antifungal agents, patients receiving fluconazole and caspofungin might be susceptible to the development of breakthrough *Rhodotorula* fungemia.[32]

Penicillium marneffei

Penicillium marneffei, the only dimorphic and human pathogenic *Penicillium* spp., is endemic in tropical Asia, especially Thailand, China, and Vietnam. It has emerged as the third most common AIDS-defining illness in parts of Southeast Asia.[26] Incidence of this disease has increased markedly after the first reported natural infection in 1973.[11] From approximately 30 cases from 1973 to 1990, this infection has risen to more than 160 reported cases by 1995.[13] In approximately 85 percent of cases, disseminated disease can begin as numerous papules with central necrosis and all on the face and neck (Fig. 207-1).[68] Lesions also can appear on the upper extremities, trunk, and lower extremities. The disease can present with nonproductive cough, generalized lymphadenopathy, fever, anemia, and weight loss.[13] Approximately half of the cases involve fungemia.[13] *P. marneffei* can mimic and often be misdiagnosed as other infections such as tuberculosis, *Pneumocystis jiroveci* pneumonia, cryptococcosis, and histoplasmosis. Most patients with human immunodeficiency virus (HIV) have a low $CD4^+$ count. *P. marneffei* has temperature-dependent dimorphic growth; below 37° C (98.6° F) it grows as mycelia (mold), with the formation of septate hyphae and bearing conidia, but at 37° C it grows in a yeastlike form. *P. marneffei* is the only dimorphic *Penicillium* spp., and the conidia in the environment likely enter through the respiratory tract and convert to the yeast form; pulmonary alveolar macrophages appear to be the primary pulmonary host defense.

An in vitro study of 30 isolates revealed susceptibility to itraconazole and ketoconazole, and intermediate activity to amphotericin B and fluconazole.[26] Two comparative in vitro studies showed that terbinafine and itraconazole had similar activity[36] and itraconazole and voriconazole possessed identical activity.[48] In another study, posaconazole showed better in vitro activity than itraconazole and amphotericin B against four isolates.[64] Micafungin showed the best in vitro activity in contrast to fluconazole, itraconazole, miconazole, and amphotericin B.[67]

Amphotericin B has been used as successful initial management of disseminated penicilliosis in immunocompromised patients, but it requires prolonged intravenous therapy and relapse is common. Amphotericin B followed by itraconazole is also effective (97.3%),[59] but itraconazole takes an average of 57 days to clear fungemia.[60] A review of 74 clinical isolates showed itraconazole generally possessed the best in vitro activity over amphotericin B, fluconazole, and ketoconazole and is generally recommended for treatment.[26]

The increasing incidence of *P. marneffei* appears to be linked to the HIV pandemic. Unlike some other emerging fungal pathogens, the infection remains sensitive to many antifungals. For severe cases, initial induction treatment with amphotericin B is necessary for 2 weeks, followed by an oral azole, such as itraconazole, for the next 10 weeks.[69] Although itraconazole is presently the azole of choice, voriconazole can be effective for chronic suppressive therapy.

MOLDS

Phaeohyphomycosis: *Cladophialophora bantiana, Bipolaris* species, and Others

Phaeohyphomycosis is a heterogeneous group of fungal diseases characterized by dematiaceous (darkly pigmented or black) hyphal forms in tissue involving the skin, subcutaneous and deep tissue, and central nervous system (CNS). The characteristic color of the hyphae is related to the presence of melanin in the fungal cell wall, which likely plays a role in fungal pathogenesis.[40] *Phaeo* comes from Greek, meaning "dark," and has been commonly used, particularly when describing infections caused by these fungi as phaeohyphomycosis. It has been suggested that the term *dematiaceous* is not appropriate given its etymologic derivation from the Greek word *deme*, meaning bundle, although it has become fairly entrenched

in medical mycology literature. The term *melanized* has become more recently used, given its specific meaning.[50] Phaeohyphomycosis has been attributed to more than 150 species of fungi, spanning several orders in the kingdom Fungi. Among the most prevalent causes of human infection are *Bipolaris* spp., *Cladophialophora bantania* (previously *Xylohypha bantania*), *Ochroconis gallopava* (previously *Dactylaria gallopava*), *Alternaria* spp., *Wangiella dermatitidis* (previously *Exophiala dermatitidis*), *Phialophora* spp., and *Curvularia* spp.[40]

C. bantiana is the etiology for the majority of CNS phaeohyphomycosis, including patients who may have no apparent immunosuppression.[12] CNS disease commonly presents with a headache and a focal neurologic deficit, frequently a hemiparesis. *Bipolaris* spp. are the most common cause of phaeomycotic sinusitis, but also may cause pneumonia, fungemia, and disseminated infections.[71] Diagnosis of phaeohyphomycosis is primarily based on histopathologic findings in affected tissue and corresponding culture.

In vitro studies with *C. bantiana* show similar low MICs for voriconazole, itraconazole, and amphotericin B.[17] One study showed posaconazole had activity slightly worse than that of itraconazole but much better than with either anidulafungin or caspofungin.[15] Another study showed itraconazole MICs better than those of voriconazole against seven isolates[48]; in another set of experiments, voriconazole had in vitro activity superior to that of itraconazole and amphotericin B.[27] The in vitro activity of drugs against *Bipolaris* spp. can give mixed results. Amphotericin B possessed better activity than voriconazole and itraconazole against *Bipolaris hawaiiensis* and *Bipolaris spicifera*.[17] However, in another study, voriconazole showed the best in vitro activity in contrast to amphotericin B, fluconazole, and itraconazole.[36] In contrast, a study with six *Bipolaris* spp. isolates showed itraconazole with the best activity, followed closely by voriconazole and amphotericin B[15] and another study with 43 isolates showed itraconazole had great in vitro activity.[35] In the evaluation of the echinocandins, itraconazole retained the best activity, with both voriconazole and posaconazole displaying good activity, and all were far better than caspofungin or anidulafungin.[14] Comparing all available triazoles, posaconazole had the most activity, followed by itraconazole, and lastly voriconazole.[45]

Including only culture-positive cases of CNS phaeohyphomycosis, the survival rate for this infection is only 35 percent.[12] CNS lesions may be best managed surgically, and a series of 30 cases revealed those patients with single, encapsulated lesions did much better than those with multifocal disease. However, no patient who did not undergo surgery survived. Whether patients underwent neurosurgery alone or with antifungal therapy, the most important factor for cure was resectability of the lesion; antifungal therapy itself was not associated with improved survival.

CNS phaeohyphomycosis continues to possess a high mortality rate without surgical resection, and this may be the case for all localized phaeohyphomycosis. The extended-spectrum triazoles such as voriconazole and posaconazole show good in vitro activity against *C. bantiana*, *Bipolaris* spp., and several other dematiaceous fungi with some positive correlating clinical experience. Although the triazoles are probably more effective, the echinocandins do have some limited activity, and these agents will likely be tried in refractory cases as combination therapy. A review of 101 cases of culture-proved CNS phaeohyphomycosis found that the most frequently isolated species was *C. bantiana*, followed by *Ramichloridium mackenziei*, which is seen exclusively in patients from the Middle East (Fig. 207-2). More than half of the cases occurred in patients with no known underlying immunodeficiency. Mortality rates were high, and therapy, although not standardized, was best with the combination of amphotericin B, flucytosine, and itraconazole. Complete excision of brain lesions may provide better results than simple aspiration, underscoring that a very aggressive medical and surgical approach is needed.[51]

FIGURE 207-2 ■ Brain computed tomography showing six enhancing lesions at initial diagnosis.

Paecilomyces *Species*

In contrast to phaeohyphomycosis, hyalohyphomycosis refers to infections caused by colorless (nonpigmented, nonmelanized) septate fungal hyphae in affected tissue. The major hyalohyphomycotic pathogens are *Fusarium* spp. and *Scedosporium* spp. (both covered in Chapter 206), *Paecilomyces* spp., and *Trichoderma* spp. These four species are often misidentified as *Aspergillus* spp., but they can be differentiated by their conidia and phialide morphologies.[40]

Paecilomyces spp. are common soil saprophytes and can be recovered from the air because they are resistant to common methods of sterilization.[40] The two most

common species associated with clinical infection are *Paecilomyces lilacinus* and *Paecilomyces variotii*. They are often confused with the *Penicillium* spp. and clinically difficult to identify because their presentation can mimic better-known fungi such as dematiaceous fungi and certain hyalohyphomycoses.[55] They can cause keratitis, endophthalmitis, and subcutaneous infections in the healthy host. In immunocompromised patients they can manifest as cutaneous disease, catheter-related fungemia, sinusitis, and disseminated disease. Many immunocompromised patients obtain infection by integument breaks with intravascular catheters or chemotherapy.[44] In fact, contaminated skin lotion has caused a nosocomial outbreak of infection in a bone marrow transplant unit.[61] Of the approximately 160 cases of invasive *Paecilomyces* spp. infection reported,[43] approximately 50 percent are keratitis or endophthalmitis.

Fungemia can be seen, similar to *Fusarium* spp. and *Acremonium* spp. When *Fusarium* spp., *Paecilomyces* spp., and *Acremonium* spp. invade tissue they produce hyphae and adventitious structures similar to microconidia that hematogenously disseminate and are discovered on blood culture.[30] *Aspergillus* does not do this, except *Aspergillus terreus*, which can elaborate lateral conidia in vitro and in vivo.[44]

Amphotericin B is very potent against *P. variotii* but has poor in vitro activity against the most common species, *P. lilacinus*. Voriconazole MICs are much lower than itraconazole against *P. lilacinus*, including superior fungicidal activity[17] which was confirmed in another study, but the reverse was true for *P. variotii*, with itraconazole activity better than voriconazole.[48] In a study with posaconazole, it was found to have activity similar to that of itraconazole and better than that of amphotericin B against *P. variotii*. Posaconazole displayed significantly better activity against *P. lilacinus* than itraconazole, and amphotericin B showed no activity against that species.[64] Comparing all triazoles, posaconazole had the most activity, followed by itraconazole, ravuconazole, and finally voriconazole.[45] Caspofungin was inactive in vitro against *P. lilacinus*, but showed excellent activity against *P. variotii*.[9] On the other hand, micafungin showed good in vitro activity against *P. lilacinus* and *P. variotii*, and better than fluconazole, itraconazole, miconazole, and amphotericin B.[67]

In an immunosuppressed murine model of disseminated infection with *P. lilacinus*, voriconazole significantly prolonged survival with respect to the group treated with amphotericin B, reducing the fungal load in the spleen, kidneys, and liver of infected mice. Survival of mice treated with amphotericin B did not differ from that of the control group, and amphotericin B was not able to reduce the tissue burden in any organ with respect to the control group.[54] In another murine model of paecilomycosis, posaconazole was superior to amphotericin B or liposomal amphotericin B and was the only treatment able to significantly reduce fungal loads in the spleen, kidneys, and liver of the mice infected by each of the two strains.[53]

The cornerstone of therapy has been surgical resection and removal of any foreign object. In vitro data suggest the triazoles might be effective treatment for *Paecilomyces* infection, but large datasets of clinical experience are lacking to support the recommendation and it remains even less clear whether the echinocandins have any place in the management of these infections.

Trichoderma longibachiatum

Trichoderma spp. are a ubiquitous component of soil microflora with five species of the genus *Trichoderma* identified as etiologic agents of infection in immunocompromised hosts: *T. longibrachiatum*, *T. harzianum*, *T. koningii*, *T. pseudokoningii*, and *T. viride*.[52] *T. longibrachiatum* causes virtually all human infections, similar to *P. marneffei* as virtually the only pathogenic *Penicillium* spp. and has been reported to cause pulmonary, cerebral, soft tissue, and disseminated disease in immunocompromised patients. It has been suggested that *T. longibrachiatum* can be acquired through the gastrointestinal tract, and prolonged therapy with fluconazole and antibacterial agents may selectively favor this filamentous fungus.[52] Another likely source may be aerosols or contaminated water.[40]

Itraconazole displays the best in vitro activity amongst older antifungals.[19,39,57,62] Other studies showed itraconazole with no activity, and amphotericin B had better activity than voriconazole.[16] However, amphotericin B resistance is uniform in reported clinical cases. The first case of *Trichoderma* infection in an immunocompromised patient was reported in 1976, and a review lists only 10 cases reported in immunocompromised hosts.[52]

Trichoderma infections appear to be slowly increasing in immunocompromised patients. Extended-spectrum triazoles should be considered over the polyenes for treatment, but recovery from immunosuppression appears crucial to success. Stool surveillance cultures for early identification of this fungus remain unproved for clinical management, but may play a role with future studies.

Acremonium *Species*

Acremonium spp. are hyalohyphomycoses, mycoses caused by filamentous fungi that have colorless septate hyphae in tissue. They are common in soil, plant debris, and rotting mushrooms. *Acremonium kiliense* is the most important among the 10 species reported as infectious etiologies in vertebrates. The immunocompetent host can form a mycetoma or develop an ocular infection after sustaining a penetrating injury.[25] *Acremonium* spp. can lead to a wide range of infections from keratitis to disseminated disease, with the lung and gastrointestinal tract as apparent portals of entry.[71]

The first case of *Acremonium* spp. infection other than mycetoma or ocular infection was described in 1932, but most have arisen since 1985.[25] The largest review of 36 localized or disseminated cases showed the majority of disseminated cases occurred in immunocompromised patients and only approximately half could be cured, with complete resolution of disease dependent on neutrophil recovery.[25] Recognition of disseminated *Acremonium* infection is difficult because specific signs and symptoms do not exist. Patients may present with a cutaneous nodule, papular skin rash, or fungemia.

In one study, itraconazole had no activity and voriconazole had a marginally effective MIC for *A. kiliense*.[48] Another study showed voriconazole with better in vitro activity than amphotericin B, fluconazole, and itraconazole for *Acremonium alabamensis* and *Acremonium strictum*.[36] Anidulafungin has no activity against *Acremonium* spp., but posaconazole and caspofungin both possess some fungistatic activity against *A. strictum*.[14] A more recent study showed voriconazole and ravuconazole with similar activity and superior to posaconazole, and the strains tested were resistant to amphotericin B and itraconazole.[45]

The rarity of *Acremonium* infections makes it difficult to adequately assess the best treatment regimen. Amphotericin B was previously recommended as initial therapy[18] and despite the in vitro resistance to azole treatment, the combination of surgery and azoles has often been successful.[25] Voriconazole appears to have the greatest in vitro activity against *Acremonium*, but clinical reports of its effectiveness are lacking. Similar to other fungal pathogens, the status of the host defense system is crucial. Acremonium infections are still rare but deadly, and the limited amount of clinical experience makes firm recommendations difficult. The echinocandins appear to have limited activity, whereas the newer triazoles may be beneficial adjunctive therapy in concert with boosting the host immune response.

SECTION **XXII**

PARASITIC DISEASES

CHAPTER 208

Classification and Nomenclature of Human Parasites

Lynne S. Garcia

Although common names frequently are used to describe parasitic organisms, these names may represent different parasites in different parts of the world. To eliminate these problems, a binomial system of nomenclature in which the scientific name consists of the genus and species is used.[1-3,8,12,14,17] These names generally are of Greek or Latin origin. In certain publications, the scientific name often is followed by the name of the individual who originally named the parasite. The date of naming also may be provided. If the name of the individual is in parentheses, it means that the person used a generic name no longer considered to be correct.

On the basis of life histories and morphologic characteristics, systems of classification have been developed to indicate the relationship among the various parasite species. Closely related species are placed in the same genus, related genera in the same family, related families in the same order, related orders in the same class, and related classes in the same phylum, one of the major categories in the animal kingdom. As one moves up the classification schema, each category becomes more broad; however, each category still has characteristics in common.

Parasites of humans are classified in a number of major divisions. They include the Protozoa (amebae, flagellates, ciliates, sporozoans, and coccidia), the Fungi (microsporidia), the Platyhelminthes or flatworms (cestodes, trematodes), the Acanthocephala or thorny-headed worms, the Nematoda or roundworms, and the Arthropoda (insects, spiders, mites, ticks, and so on). Although these categories appear to be well defined, often considerable confusion occurs in attempting to classify parasitic organisms. One of the primary reasons is the lack of known specimens. Some organisms recovered from humans are very rare; thus, difficulty arises in determining morphologic and physiologic variation among such groups. Type specimens must be deposited for study before a legitimate species name can be given. Even when certain parasites are numerous, they may represent strains or races of the same species with slightly different characteristics.

In general, reproductive mechanisms are a valid concept in determining definitions of species, but so many exceptions exist within parasite groups that taking into consideration properties such as sexual reproduction, parthenogenesis, and asexual reproduction is difficult. Another difficulty in recognition of species is the ability and tendency of the organisms to alter their morphologic forms according to age, host, or nutrition, which often results in several names being given to the same organism. An additional problem involves alternation of parasitic and free-living phases in the life cycle. These organisms may be very different and difficult to recognize as belonging to the same species. Despite these difficulties, newer, more sophisticated molecular methods of grouping organisms often have confirmed taxonomic conclusions reached hundreds of years earlier by experienced taxonomists.

As investigations continue in parasitic genetics, immunology, and biochemistry, the species designation will be defined more clearly. Originally, these species designations were determined primarily by morphologic differences, resulting in a phenotypic approach. With the use of highly sophisticated molecular techniques, the approach will continue to be more genotypic. Benefits of these studies also include the development of highly specific and sensitive diagnostic tests and the ability to diagnose parasitic infections on the basis of molecular parameters rather than merely phenotypic characteristics.

Although gaps in our knowledge concerning classification of all human parasites remain, the binomial system has allowed the classification of 1.5 million species of organisms in the animal kingdom such that all published information can be retrieved, regardless of the language spoken. The difficulty for the clinician arises when one considers the rapid increase in information concerning microbiology during the past few years and changing considerations, such as the role of immunosuppression in the host-parasite interaction and the modified definitions of "normal flora" and "nonpathogenic" in this population of patients.

The classification of parasites is presented in tabular form. Although certain designations of species may be somewhat controversial, this classification scheme is designed to provide some order and meaning to a widely divergent group of organisms. No attempt has been made to include every possible organism, and only those considered clinically relevant in the context of human parasitology are listed. The main groups that are presented include protozoa, fungi, nematodes (roundworms), cestodes (tapeworms), and trematodes (flukes). Some relevant information on arthropods is presented in Tables 208-1 and 208-2. The hope is that this information will provide some insight into the parasite groupings, thus leading to a better understanding of parasitic infections and the appropriate diagnostic and clinical approach.

TABLE 208-1 **Human Vector-Borne Infections**

Infection (Disease)	Causative Agent	Vector (Common Name)
Protozoal		
Malaria	*Plasmodium* spp.	Mosquitoes
Leishmaniasis	*Leishmania* spp.	Sandflies
Chagas disease	*Trypanosoma cruzi*	Triatomid bugs
East African trypanosomiasis	*Trypanosoma brucei rhodesiense*	Tsetse flies
West African trypanosomiasis	*Trypanosoma brucei gambiense*	Tsetse flies
Babesiosis	*Babesia* spp.	Ticks
Helminthic		
Filariasis	*Wuchereria bancrofti*	Mosquitoes
Filariasis	*Brugia malayi*	Mosquitoes
Filariasis	*Dirofilaria* spp.	Mosquitoes
Filariasis	*Mansonella perstans*	Biting midges
Filariasis	*Mansonella streptocerca*	Biting midges
Filariasis	*Mansonella ozzardi*	Biting midges
Onchocerciasis	*Onchocerca volvulus*	Black flies
Loiasis	*Loa loa*	Deer flies
Dog tapeworm infection	*Dipylidium caninum*	Dog lice and fleas, human fleas
Rat tapeworm infection	*Hymenolepis diminuta*	Rat fleas, beetles, grain beetles
Dwarf tapeworm	*Hymenolepis nana*	Grain beetles (rare)

PROTOZOA

Amebae—Intestinal

These organisms are characterized by having pseudopods (motility) and trophozoite and cyst stages in the life cycle and include some exceptions in which a cyst form has not been identified. Amebae usually are acquired by humans through fecal-oral transmission or mouth-to-mouth contact (*Entamoeba gingivalis*).

Current Name

*Entamoeba histolytica**
*Entamoeba dispar**
Entamoeba hartmanni†
Entamoeba coli
Entamoeba polecki
Entamoeba moshkovskii
Entamoeba gingivalis
Endolimax nana
Iodamoeba bütschlii
*Blastocystis hominis**

Flagellates—Intestinal

These organisms move by means of flagella and are acquired by fecal-oral transmission. With the exception of *Dientamoeba fragilis* (internal flagella) and those in the genera *Trichomonas* and *Pentatrichomonas*, they have the trophozoite and cyst stages in the life cycle. *D. fragilis*, *Trichomonas*, and *Pentatrichomonas* species do not have a cyst stage.

Current Name

Giardia lamblia†
Chilomastix mesnili
Dientamoeba fragilis
Pentatrichomonas hominis
Trichomonas tenax

**Entamoeba histolytica* is being used to designate the true pathogen, whereas *Entamoeba dispar* now is being used to designate a nonpathogen. Unless trophozoites containing ingested red blood cells (*E. histolytica*) are seen during microscopic examination, the two organisms cannot be differentiated on the basis of morphologic features seen in permanent stained smears of fecal specimens and will be reported as *E. histolytica/E. dispar*. Fecal immunoassays for antigen detection are available commercially for differentiation of *E. histolytica* from *E. dispar* and for detection of the *E. histolytica/E. dispar* group.[7] Because the differences in pathogenicity are genetic and not just phenotypic, the decision to treat is one that must be determined by the physician. The finding of organisms in the *E. histolytica/E. dispar* group in patient specimens must continue to be reported to state and county Departments of Public Health (follow your particular state reporting regulations).

†*Entamoeba hartmanni* is nonpathogenic and is totally different from *E. histolytica*. "Small race *E. histolytica*" is incorrect and should not be used at any time to designate *E. hartmanni*.

*The taxonomic position of *Blastocystis* has always been somewhat confusing, but it is now clear that this organism exists as a number of serotypes or species. It has been recommended that all isolates from birds and mammals, including humans, be designated in the future as *Blastocystis* spp., serotypes ST1 to ST10 plus ST Unknown. This organism has now been placed in the Stramenopila.[21]

†Although some individuals have changed the species designation for the genus *Giardia* to *G. duodenalis* or *G. intestinalis*, no consensus exists. Therefore, for this listing, the name *Giardia lamblia* is retained. However, molecular and epidemiologic evidence suggests that at least two assemblages of *Giardia* infect humans, one of which is *Giardia duodenalis* and the other, possibly a new species, *Giardia enterica*.[16]

TABLE 208-2 **Medically Important Arthropods**

Local or Systemic Problems	Vector (Common Name)
Skin reaction to bites	Sucking lice
	Bedbugs
	Kissing bugs
	Biting midges
	Sandflies
	Black flies
	Mosquitoes
	Deer flies
	Tsetse flies
	Soft ticks
	Hard ticks
Painful bite	Horseflies
	Fire ants
	Centipedes
Intense itching	Human itch mites
	Chiggers
Painful sting, potential anaphylaxis	Honeybees
	Bumblebees
	Wasps, hornets, yellow jackets
	Fire ants
	Scorpions
Dermatitis, ulcerations	Fleas
Nodular ulceration with subsequent secondary infection	Chigoe flea
Blistering of skin after contact with adult beetles	Blister beetles
Bite, usually painless, delayed systemic reaction	Black widow spiders
Initial blister followed by extensive necrosis and slow healing	Brown recluse spiders
	South American brown spider

Enteromonas hominis
Retortamonas intestinalis

Ciliates—Intestinal

These organisms, which move by means of cilia, are acquired by humans through fecal-oral transmission. They have both the trophozoite and cyst forms in the life cycle.

Current Name

Balantidium coli

Apicomplexa, Sporozoa (Coccidia)—Intestinal

These organisms are acquired by humans by ingestion of various meats or through fecal-oral transmission through contaminated food or water.

Current Name

Coccidia
Cryptosporidium hominis
Cryptosporidium parvum
Cryptosporidium spp.
Cyclospora cayetanensis[18,19]
Isospora (Cystoisospora) belli
Sarcocystis hominis
Sarcocystis suihominis
Sarcocystis bovihominis

Fungi (Microsporidia*)—Intestinal

Enterocytozoon bieneusi
Encephalitozoon (Septata) intestinalis†

Amebae, Flagellates—Other Body Sites

The amebae are pathogenic, free-living organisms that may be associated with warm, freshwater areas. They have been found in the central nervous system, the eye, and other sites. *Trichomonas vaginalis* usually is acquired by sexual transmission. This particular flagellate is found in the genitourinary system.

Current Name

Amebae
Naegleria fowleri
Acanthamoeba spp.
Hartmannella spp.
Balamuthia mandrillaris
Sappinia diploidea
Flagellates
Trichomonas vaginalis

Apicomplexa, Sporozoa (Coccidia)—Other Body Sites

The coccidia are particularly important in the compromised patient. They also may infect many individuals who have no apparent symptoms.[6,7] On the basis of molecular studies, the microsporidia are linked more closely to the fungi and have been reclassified with those organisms. However, during this transition phase, the listing will remain with the parasites.

Current Name

Coccidia
Toxoplasma gondii

*The microsporidia are now thought to be more closely related to fungi than to protozoa; however, parasitologists have been reluctant to part with this group, whereas mycologists have been equally reluctant to accept it. Consequently, the microsporidia will be retained within this list for parasites, although they are classified within the Fungi.[11,22,23]
†Formerly called *Septata intestinalis*.[10,15]

Fungi (Pneumocystis,* Microsporidia)—Other Body Sites

Microsporidia
- *Nosema ocularum*
- *Anncaliia (Brachiola) connori*
- *Anncaliia (Brachiola) algerae*
- *Anncaliia (Brachiola) vesicularum*
- *Vittaforma corneae*
- *Pleistophora ronneafiei*
- *Trachipleistophora hominis*
- *Trachipleistophora anthropophthera*
- *Encephalitozoon hellem*
- *Encephalitozoon cuniculi*
- *Encephalitozoon (Septata) intestinalis*†
- *Enterocytozoon bieneusi*‡
- *Microsporidium africanum*§
- *Microsporidium ceylonensis*
- *Tubulinosema acridophagus*¶

Sporozoa, Flagellates—Blood and Tissues

All of these organisms are arthropod borne. Diagnosis may be somewhat more difficult to make than is that of the intestinal protozoa, particularly if automated blood differential systems are used. The *Leishmania* have undergone extensive revisions in classification. However, from a clinical perspective, recovery and identification of the organisms still are related to body site. Recovery of the organisms is limited to the site of the lesion in infections other than those caused by the *Leishmania donovani* complex (visceral leishmaniasis).

Current Name

Apicomplexa, Sporozoa (malaria, babesiosis)
- Malaria
  - *Plasmodium vivax*
  - *Plasmodium ovale*
  - *Plasmodium malariae*
  - *Plasmodium falciparum*
  - *Plasmodium knowlesi***
- Babesiosis*
  - *Babesia microti*
  - *Babesia divergens*
  - *Babesia duncani*
  - *Babesia* spp.

Flagellates (leishmaniasis, trypanosomiasis)
- Leishmaniasis
  - *Leishmania tropica* complex (cutaneous leishmaniasis)
  - *Leishmania infantum* complex (cutaneous leishmaniasis)
  - *Leishmania major* complex (cutaneous leishmaniasis)
  - *Leishmania mexicana* complex (cutaneous leishmaniasis)
  - *Leishmania braziliensis* complex (mucocutaneous leishmaniasis)
  - *Leishmania donovani* complex (visceral leishmaniasis)
  - *Leishmania infantum/Leishmania chagasi* group (visceral leishmaniasis)
- Trypanosomiasis
  - *Trypanosoma brucei gambiense* (West African trypanosomiasis)
  - *Trypanosoma brucei rhodesiense* (East African trypanosomiasis)
  - *Trypanosoma cruzi* (American trypanosomiasis)
  - *Trypanosoma rangeli*

NEMATODES

Nematodes—Intestinal

These organisms normally are acquired by ingestion of eggs or penetration of the skin by larval forms from the soil.

Current Name

- *Ascaris lumbricoides*
- *Enterobius vermicularis* (pinworm)
- *Ancylostoma duodenale*
- *Necator americanus*
- *Strongyloides stercoralis*
- *Strongyloides fuelleborni*
- *Trichostrongylus* spp.
- *Trichuris trichiura* (whipworm)
- *Capillaria philippinensis*
- *Oesophagostomum* spp. (*O. bifurcum* most common in humans—West Africa)
- *Ternidens diminutus* (as high as 80% in Zimbabwe)

Nematodes—Tissue

For the most part, these organisms rarely are seen within the United States; however, the first three are more important.

**Pneumocystis carinii* has been reclassified with the fungi and renamed *Pneumocystis jiroveci*.[5,20] Consequently, it will be removed from future parasite listings.

†Formerly called *Septata intestinalis.*

‡*Enterocytozoon bieneusi* has been recovered from sites other than the intestinal tract.

§This designation is now written as a true genus but remains a "catch-all" for those organisms that have not been (or may never be) identified to the true genus or species levels.

¶New human pathogen, disseminated infection in a patient with multiple myeloma (severely immunosuppressed, allogeneic stem cell transplant recipient).[13]

***Plasmodium knowlesi*, a malaria parasite of macaque monkeys in Southeast Asia that is now established as a naturally transmitted parasite of humans in Malaysia and other parts of Southeast Asia, has been responsible for a number of deaths.[4] Thus, there are now five species of malaria that infect humans.

*Molecular studies confirm that humans can also harbor a number of *Babesia* parasites that have not yet been identified.[9]

Current Name

Trichinella spiralis
Trichinella spp.
Toxocara canis or *Toxocara cati* (visceral or ocular larva migrans)
Ancylostoma braziliense (cutaneous larva migrans)
Ancylostoma caninum (eosinophilic enteritis)
Baylisascaris procyonis (severe systemic visceral larva migrans, neural larva migrans)
Dracunculus medinensis
Angiostrongylus cantonensis
Angiostrongylus costaricensis
Gnathostoma spinigerum
Gnathostoma spp.
Anisakiasis (larvae from saltwater fish)
Anisakis spp.
Phocanema spp.
Contracaecum spp.
Pseudoterranova spp.
Hysterothylacium spp.
Porrocaecum spp.
Capillaria hepatica
Thelazia spp.

Nematodes (Filarial Worms)—Blood, Other Body Fluids, Skin

These organisms also are arthropod borne. The adult worms tend to live in the tissues of lymphatics. Diagnosis is made on the basis of the recovery and identification of the larval worms (microfilariae) in the blood, other body fluids, or skin. Elephantiasis may be associated with some of the organisms listed.

Current Name

Wuchereria bancrofti
Brugia malayi
Brugia timori
Loa loa
Onchocerca volvulus
Mansonella ozzardi
Mansonella streptocerca
Mansonella perstans
Dirofilaria immitis ("coin" lesion in the lung) (dog heartworm)
Dirofilaria spp. (may be found in subcutaneous nodules)

CESTODES

Cestodes—Intestinal

The adult form of these organisms is acquired by humans through ingestion of the larval forms contained in poorly cooked or raw meats or freshwater fish. In the case of *Dipylidium caninum*, infection is acquired by the accidental ingestion of dog fleas. Both *Hymenolepis nana* and *Hymenolepis diminuta* are transmitted by ingestion of certain arthropods (fleas, beetles). Also, *H. nana* can be transmitted through egg ingestion (life cycle in the human can bypass the intermediate beetle host). Humans can serve as both the intermediate and definitive hosts in *H. nana* and *Taenia solium* infections.

Current Name

Diphyllobothrium latum (broad, fish tapeworm)
Dipylidium caninum (dog tapeworm)
Hymenolepis (Rodentolepis) nana (dwarf tapeworm)
Hymenolepis diminuta (rat tapeworm)
Taenia solium (pork tapeworm)
Taenia saginata (beef tapeworm)
Taenia asiatica (Taiwanese variant of *T. saginata*)

Cestodes (Larval Forms)—Tissue

The ingestion of certain tapeworm eggs or accidental contact with certain larval forms can lead to the diseases shown in parentheses.

Current Name

Taenia solium (cysticercosis)
Echinococcus granulosus (hydatid disease)
Echinococcus multilocularis (alveolar hydatid disease)
Echinococcus oligarthrus (polycystic hydatid disease)
Multiceps multiceps (coenurosis)
Diphyllobothrium spp. (sparganosis)
Spirometra mansonoides (sparganosis)

TREMATODES

Trematodes—Intestinal

These organisms are uncommon within the United States, except for four species of *Alaria*, which are endemic within North America.

Current Name

Fasciolopsis buski (giant intestinal fluke)
Echinostoma ilocanum
Eurytrema pancreaticum
Heterophyes heterophyes
Metagonimus yokogawai
Alaria spp.

Trematodes—Liver, Lung

These organisms are not seen commonly within the United States; however, some Southeast Asian refugees do harbor some of these parasites.

Current Name

Clonorchis (Opisthorchis) sinensis (Chinese liver fluke)
Opisthorchis viverrini
Opisthorchis felineus
Fasciola hepatica (sheep liver fluke)
Paragonimus westermani (lung fluke)

Paragonimus kellicotti (lung fluke endemic in the United States)
Paragonimus spp.
Metorchis conjunctus (North American liver fluke)

Trematodes—Blood

The schistosomes are acquired by penetration of the skin by the cercarial forms that are released from freshwater snails. Although they are not endemic within the United States, occasionally patients are seen who may have these infections.

Current Name

Schistosoma mansoni
Schistosoma haematobium
Schistosoma japonicum
Schistosoma intercalatum
Schistosoma mekongi

ARTHROPODS

See Tables 208-1 and 208-2.

SUBSECTION 1 *PROTOZOA*

CHAPTER 209

Amebiasis

Shinjiro Hamano • William A. Petri, Jr.

Diarrheal diseases continue to be major causes of morbidity and mortality in children in developing countries. In Bangladesh, 10 percent of children in the first year of life have amebic diarrhea and 1 in 30 children dies of diarrhea or dysentery by age 5 years.[78] Amebiasis is an infection caused by the protozoan parasite *Entamoeba histolytica*. Infection occurs via ingestion of the parasite's cyst from fecally contaminated food, water, or hands. Approximately 50 million illnesses and 100,000 deaths occur annually from amebiasis, rendering it the third leading cause of death by parasitic disease in humans.[78] Although amebiasis is present worldwide, it occurs most commonly in underdeveloped areas, especially Asia, sub-Saharan Africa, and Central and South America. In the United States and other developed countries, cases of amebiasis are most likely to occur in immigrants from and travelers to endemic regions, but it can affect populations of the developed world, as shown by the epidemic that occurred

in Tbilisi, Republic of Georgia, caused by contaminated municipal water.[13] Currently, there is no vaccine to prevent the childhood morbidity and mortality resulting from infection with *E. histolytica*.

ETIOLOGY

E. histolytica is the cause of amebiasis and was named for the pathologic evidence of "lysis" of tissues. Additional *Entamoeba* spp. that infect humans and that are identical in appearance microscopically to *E. histolytica* include *E. dispar*, which is nonpathogenic, *E. moshkovskii*, which may cause diarrhea,[95] and the recently identified enteric parasite *E. bangladeshi*.[91] The first demonstration of the organism in human tissues was made by Lambl in 1859 in the postmortem examination of the colon of a child who died as a result of having excessive diarrhea.[16,74] No connection of the organism with the disease was made until 1875, when Losch, in St. Petersburg, Russia, found the organism at autopsy in the colon of a woodcutter. Losch induced diarrhea and ulcerations in a dog given feces from the patient.[61] He did not think, however, that a connection existed between the organism and the disease. The first patient described in the United States was a physician treated by Osler for an amebic liver abscess in 1890.[74] Councilman and Lafleur described the organism and the disease in 1891.[20,45] Further investigation of the disease was delayed until a better understanding of the life cycle of *E. histolytica* could be obtained.[27] In recent years, the application of modern molecular biology techniques to the study of *E. histolytica* and *E. dispar* has resulted in an explosion of information about the mechanisms of virulence, pathogenicity, and immune responses to these organisms.[88,90]

E. histolytica is the pathogenic species, having the capacity to invade tissue and cause symptomatic disease, whereas *E. dispar* (and *E. histolytica*) is associated with the asymptomatic carrier state.[6,88] More recently, a study revealed that all genotypes of *E. histolytica* are not equally capable of causing disease.[6] Morphologically distinct members of the genus *Entamoeba*, such as *Entamoeba coli* and *Entamoeba hartmanni*, also are nonpathogenic. *Entamoeba moshkovskii*, *Dientamoeba fragilis*, and *Entamoeba polecki* have been associated with diarrhea, and *Entamoeba gingivalis* has been associated with periodontal disease.

Members of the genus *Entamoeba*, which are protozoan organisms belonging to the subphylum Sarcodina and close to *Dictyostelium discoideum* on one of the lowest branches of the eukaryotic tree, have trophozoite and cyst forms.[39] The cysts of *E. histolytica*, *E. dispar*, *E. moshkovskii*, and *E. bangladeshi* are almost spherical, being surrounded by a cell wall composed of chitin. The cysts may have one to four nuclei, although quadrinucleate cysts are most typical. This feature allows differentiation from *Escherichia coli*, which usually has 6 to 8 nuclei in the cysts and may have 32 nuclei.[75] Cysts of *E. histolytica* are 5 to 20 μm in diameter (average, 12 μm) and have a greenish tint in the unstained condition.[62] Young cysts contain chromatoid bodies, which are composed of ribosome particles in crystalline arrays.[12] The cysts of *E. hartmanni* appear identical to those of *E. histolytica* except for being a smaller size (4 to 10 μm). *E. histolytica* cysts can survive for days in the dried state at 30° C or for months at 0° C to 4° C. They can be killed by temperatures greater than 50° C retained for 5 minutes.[45] They are completely resistant to the concentrations of chlorine used in water supplies but may be killed with hyperchlorination or with iodine solutions.[62,75] They are filtered from water supplies that pass through a sand filtration phase. They resist acids well.

When these quadrinucleate cysts are ingested, they resist the acid pH of the stomach and ultimately excyst in the alkaline environment of the bowel. The process of excystation results in the release of four trophozoites that divide by binary fission to produce eight trophozoites. The usual trophozoites have a diameter of 25 μm (range, 10 to 60 μm).[27,88] They have a single nucleus that is 3 to 5 μm in diameter and contains fine peripheral chromatin with a slightly eccentric karyosome. They have a granular endoplasm that typically contains vacuoles in which bacteria and debris can be seen. Some glycogen is present and can be stained with periodic acid–Schiff stain.

Although amebae were thought to lack organelles, such as mitochondria, endoplasmic reticulum, and Golgi apparatus, evidence to the contrary is coming to light. The existence of nuclear-encoded mitochondrial genes and a remnant mitochondrial organelle was reported more recently.[63,102] The presence of ingested erythrocytes is a characteristic feature of *E. histolytica* but not *E. dispar*.[88] Movement is accomplished by extension of clear pseudopodia. Replication is by binary fission. These protozoa live in the colon of humans and other mammals. Trophozoites die quickly outside the body and are quite sensitive to acid—they generally are not considered to be infective.[32] When cooled (as when feces are expelled and gradually cooled from body temperature) or stimulated by as-yet-undefined luminal conditions, the trophozoites form cysts that can remain viable for weeks to months on excretion.[88]

Trophozoites of *E. coli* are 15 to 50 μm in diameter; have much more sluggish motility than the trophozoites of *E. histolytica;* and have blunt pseudopodia, rather than the sharp, finger-like pseudopodia of *E. histolytica*. Trophozoites of *E. hartmanni* are 4 to 14 μm in diameter and have much less glycogen than the trophozoites of *E. histolytica*.[27]

EPIDEMIOLOGY

Amebiasis is distributed throughout the world. The number of people infected with either *E. histolytica* or *E. dispar* per year is estimated to be 500 million. Although most individuals remain asymptomatic, perpetuating the natural cycle of the organism through fecal excretion of infective cysts, approximately 50 million people experience the severe morbidity associated with invasive disease, with an estimated 100,000 dying annually.[78,99] In the United States, 50 percent of amebiasis is observed in Hispanics, Asians, and Pacific Islanders. Travelers from developing countries, malnourished individuals,[72] men, and residents of institutions for the mentally retarded are considered to be at higher risk for amebiasis (Table 209-1).

TABLE 209-1 Risk Factors for Amebiasis in the United States

Hispanic/Asian/Pacific Islanders—50% of U.S. cases reported to CDC
Travelers to endemic regions of the world—0.3% incidence in one study
Institutions for mentally retarded
Men who have sex with men
Men—90% amebic liver abscesses in men, but rare in children

CDC, Centers for Disease Control and Prevention.

During the 1990s, enough evidence had accumulated to support the formal separation of two morphologically identical species of ameba: the nonpathogenic *E. dispar* from the potentially pathogenic *E. histolytica*.* Morbidity and mortality data in absolute numbers that existed before this time pertaining to cases of invasive disease were not greatly affected by this reclassification because all invasive disease was known to be caused by *E. histolytica*.[99] Because most prevalence and incidence data previously collected pertained to asymptomatic individuals, however, and it was clear that most asymptomatic individuals with cysts detected in their stool were infected with nonpathogenic *E. dispar*, the true prevalence and incidence of *E. histolytica* became a matter of speculation.[99]

Estimates of *E. histolytica* infections have been based primarily on examinations of stool for cysts and parasites, but these tests are insensitive and cannot differentiate *E. histolytica* from morphologically identical species that are nonpathogenic, such as *E. dispar* and *Entamoeba moshkovskii*.[5,22] Specific and sensitive means to detect *E. histolytica* in stool are now available and include antigen detection and polymerase chain reaction (PCR) analysis.[36,44,58]

A prospective study of preschool children in a slum of Dhaka, Bangladesh, showed *E. histolytica*–associated diarrhea in 9 percent and *E. histolytica*–associated dysentery in 3 percent of the children annually.[42] Not all individuals are equally susceptible to amebiasis, with a leptin receptor polymorphism and certain HLA-DR and HLA-DQ alleles associated with resistance to infection and disease.[23,24] The annual incidence of amebic liver abscess was reported to be 21 cases per 100,000 inhabitants in Hue City, Vietnam.[14] Carefully conducted serologic studies in Mexico, where amebiasis is endemic, showed antibody to *E. histolytica* in 8.4 percent of the population.[17] In the urban slum of Fortaleza, Brazil, 25 percent of all individuals tested carried antibody to *E. histolytica;* the prevalence of anti-amebic antibodies in children 6 to 14 years old was 40 percent.[15]

PATHOGENESIS AND PATHOLOGY

The cysts are transported through the digestive tract to the intestine, where they release their mobile, disease-producing form, the trophozoite. *E. histolytica* trophozoites can live in the large intestine and form new cysts without causing disease. They also can invade the lining of the colon, killing host cells and causing diarrhea, amebic colitis, acute dysentery, or chronic diarrhea. The trophozoites also can be carried through the blood to other organs, most commonly the liver and occasionally the brain, where they form potentially life-threatening abscesses (Fig. 209-1). Important virulence factors include the trophozoite cell surface galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)–specific lectin that mediates adherence to colonic mucins and host cells,[77,89] cysteine proteinases that likely promote invasion by degrading extracellular matrix and serum components, and amebapore pore-forming proteins involved in killing of bacteria and host cells.[59,92]

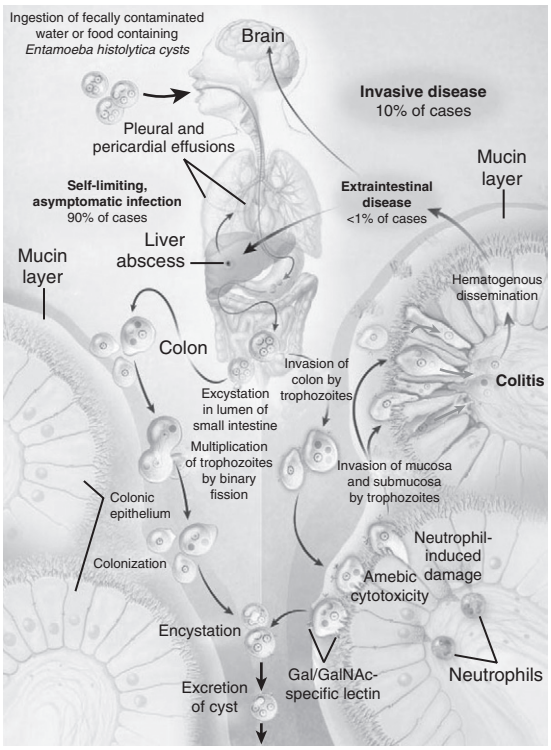

FIGURE 209-1 ■ Life cycle of *Entamoeba histolytica.* Infection normally is initiated by the ingestion of fecally contaminated water or food containing *E. histolytica* cysts. The infective cyst form of the parasite survives passage through the stomach and small intestine. Excystation occurs in the bowel lumen, where motile and potentially invasive trophozoites are formed. In most infections, the trophozoites aggregate in the intestinal mucin layer and form new cysts, resulting in a self-limited and asymptomatic infection. In some cases, adherence to and lysis of the colonic epithelium, mediated by the galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)–specific lectin, initiates invasion of the colon by trophozoites. Neutrophils responding to the invasion contribute to cellular damage at the site of invasion. When the intestinal epithelium is invaded, extraintestinal spread to the peritoneum, liver, and other sites may follow. Factors controlling invasion, as opposed to encystation, most likely include parasite "quorum sensing" signaled by the Gal/GalNAc-specific lectin, interactions of amebae with the bacterial flora of the intestine, and innate and acquired immune responses of the host. (From Haque R, Huston CD, Hughes E, et al. Amebiasis. *N Engl J Med* 2003;**348**:1565-73.)

*References 1, 14, 30, 31, 38, 99.

The interface of the Gal/GalNAc lectin with the host mucins lining the intestine is the defining moment of the infection.[19] If the parasite lectin attaches to the host mucin glycoproteins that line the intestinal lumen, a noninvasive gut infection ensues. The life cycle continues as the trophozoites reproduce by clonal expansion in the mucin layer. Subsequently, the Gal/GalNAc lectin, along with mucin glycoproteins or other gut bacteria, initiates the developmental pathway leading to encystment.[26,99]

Colitis is caused when the trophozoite penetrates the intestinal mucous layer, which otherwise acts as a barrier to invasion by inhibiting amebic adherence to the underlying epithelium and by slowing trophozoite motility.[19] Invasion is mediated by the killing of epithelial cells, neutrophils, and lymphocytes by trophozoites, which occurs only after the parasite lectin engages host GalNAc on O-linked cell surface oligosaccharides.[78] The interaction of the lectin with glycoconjugates is stereospecific and multivalent.[107] The identity of the high-affinity intestinal epithelial cell receptor is unknown. Secretion of amebapore, a 5-kDa pore-forming protein, by the ameba may contribute to killing.[57] Activation of human caspase 3, a distal effector molecule in the apoptotic pathway, occurs rapidly after amebic contact, and caspases are required for cell killing in vitro and for the formation of amebic liver abscesses in vivo.[47,106]

Interaction of the parasite with the intestinal epithelium causes an inflammatory response marked by the activation of nuclear factor κB and the secretion of cytokines.[25,93] The development of this epithelial response may depend on trophozoite virulence factors, such as cysteine proteinase, and leads to intestinal abnormalities through neutrophil-mediated damage. Neutrophils also can be protective, and activation of neutrophils or macrophages by tumor necrosis factor-α or interferon-γ kills amebae in vitro and limits the size of amebic liver abscesses.[7,21] In contrast to the intense inflammatory response typical of early invasive amebiasis, inflammation surrounding well-established colonic ulcers and liver abscesses is minimal, given the degree of tissue damage.[16]

The initial lesions of clinical amebiasis often are small interglandular ulcers with a diameter of approximately 1 mm. They extend only to the muscularis mucosa.[16,66] The margins may be hyperemic, and slight edema of the surrounding mucosa is present. *E. histolytica* organisms seen in these ulcers stain well with periodic acid–Schiff stain.[79] Bleeding and friability are not prominent at this stage, although proctoscopic examination may find mucus coming from these ulcers, with an abundant number of amebae present.

The next stage of intestinal disease is the production of deeper ulcers. These "buttonhole" ulcers may be 1 cm in diameter and may extend into the submucosa.[16,79] The ulcer often extends laterally under normal-appearing mucosa, forming a characteristic flask shape. Occasional perforation through the serosa leads to peritonitis or pneumoperitoneum.[96] Extensive necrosis may be present, but usually only very little inflammation occurs. The edema is more intense, but the mucosa between ulcers is normal, in contrast to the marked inflammatory response seen in bacterial enteritis. When ulceration is more extensive, the edema surrounding the ulcers becomes confluent and the mucosa appears gelatinous. In young children, this condition can progress to a fulminant necrotizing colitis associated with transmural necrosis. The pathologic events associated with this phenomenon are not understood. Rarely, an inflammatory response is present, resulting in granulation of the tissue with a fibrous outer wall.[75] It is given the name *ameboma*. Occasionally, an ameboma fills a significant portion of the lumen, which causes stricture or obstruction. Other complications of intestinal amebiasis result from direct extension of the ulcers. This extension may result in cutaneous involvement of the perianal area or lesions of the penis, vulva, vagina, or cervix.[2,75] Cutaneous and ophthalmologic amebiasis also is caused by fecal contamination of the face.[69]

Amebae disseminate to the liver in 50 percent of patients with fulminant amebiasis.[2,3] Dissemination to other organs directly from the intestine probably does not occur, but dissemination from the liver to lung, heart, brain, spleen, scapula, larynx, stomach, and aorta has been described.[16] Amebic abscess of the liver occurs more often in men than in women by a ratio of 16:1 but occurs equally often in prepubertal children of both sexes.[3,16] Abscesses occur more commonly in adults but occur in children as young as 4 months of age.[73] These abscesses vary from microscopic lesions to massive necrosis of 90 percent of the liver. Fever, right upper quadrant pain, and the presence of serum antibodies to amebae point to hepatic amebic abscess.[87] Examination of the fluid from such an abscess frequently reveals a reddish, "anchovy paste" fluid that rarely may appear white or green. The fluid is acidic, with a pH ranging from 5.2 to 6.7.[85] Amebae are found in the walls of the abscess and only rarely in the fluid of the abscess. Many patients with amebic liver abscess also have anaerobic bacteria in the abscess fluid.[86] The walls are composed of a thin connective tissue capsule. The right lobe of the liver is involved with amebic liver abscess about six times as often as the left lobe. Abscesses in the right lobe can perforate and cause disease below the diaphragm or in the thoracic cavity. Abscesses in the left lobe can lead to pericardial effusions, which are less common than pleural effusions.[34,49]

Pleural effusions can remain loculated or lead to cutaneous fistulas or to bronchopleural fistulas. Drainage from these fistulas is acidic, in contrast to the neutral secretions in the normal lung. Seeding of the cardiac valves and of the brain has been described.[16] Cerebral abscesses have the same microscopic findings as do liver abscesses, with a thin capsule of connective tissue surrounding a fluid with little or no associated inflammatory response.

IMMUNITY

Protection from amebiasis, including acquired immunity to infection and invasion by *E. histolytica*, is associated with a mucosal IgA antibody response against the carbohydrate recognition domain of the parasite Gal/GalNAc lectin.[33,37,39,55] Cell-mediated immunity in protection

from invasive amebiasis, but not infection per se, also has been shown. There is substantial evidence from an in vitro animal model and most recently from human studies of an important role for interferon-γ and IL-17 in protection from amebic colitis, acting in part by activating of macrophages to kill the parasite.[33,43,46] Invasive amebiasis rarely occurs in individuals with human immunodeficiency virus infection/acquired immunodeficiency syndrome, even in areas where amebiasis is common, suggesting an important role also exists for natural immunity or innate immune responses, or both, in protection from infection.[7,36]

CLINICAL MANIFESTATIONS

Intestinal Amebiasis

Asymptomatic Intraluminal Amebiasis

The most common type of amebic infestation is an asymptomatic cyst-passing carrier state. All *E. dispar* infections and 90 percent of *E. histolytica* infections are asymptomatic, manifesting as only *Entamoeba* cysts in the feces.[30,81]

Entamoeba histolytica–*Associated Diarrhea*

Diarrhea is the most common manifestation of amebic disease, present in 9 percent of children in the Mirpur cohort each year, compared with only 3 percent of children having amebic colitis each year.[42] *E. histolytica*–associated diarrhea is defined as three or more unformed stools in a 24-hour period accompanied by a new episode of *E. histolytica* infection. This definition was validated previously in the cohort by (1) showing that diarrhea was approximately five times more common in the setting of a new infection (age-adjusted odds ratio for the association of new *E. histolytica* infection with diarrhea of 4.7; 95% confidence interval 2.9 to 7.6), and (2) showing by a complete bacteriologic, virologic, and parasitic workup that only 32 percent of patients with *E. histolytica*–associated diarrhea were coinfected with another pathogen compared with identification of an enteropathogen in 59 percent of all cases of diarrhea.[39]

Acute Amebic Colitis

Amebic dysentery was defined as a diarrheal stool sample containing occult or gross blood that was positive for *E. histolytica* antigen. Seventy percent of patients have a gradual onset of symptoms over 3 or 4 weeks after infestation, with increasingly severe diarrhea as the primary complaint, accompanied by general abdominal tenderness. Occasionally, the onset may be acute or may be delayed for several months after infestation. This onset differs from bacterial causes of dysentery, in which patients usually have only symptoms of 1 to 2 days' duration. The diarrhea is usually associated with pain in children. Pain may be of such severity that an acute abdomen is suspected.[50,79] The stools contain blood and mucus in virtually all cases.[2,79,80] Fever is present in only a few patients with amebic colitis. Abdominal distention and dehydration occur in less than 10 percent of patients. In young children, intussusception, perforation, peritonitis, or necrotizing colitis may develop rapidly.[10,50,96] Amebic colitis has been shown to be associated with cognitive disability as a long-term sequelae.[101]

Ameboma

Unusual manifestations of amebic colitis include toxic megacolon (0.5% of cases, usually requires surgical intervention), ameboma (granulation tissue in colonic lumen mimicking colonic cancer in appearance), and a chronic nondysenteric form of infection that can manifest as years of waxing and waning diarrhea, abdominal pain, and weight loss (easily misdiagnosed as inflammatory bowel disease).

Extraintestinal Amebiasis

Amebic Liver Abscess

The typical patient with an amebic liver abscess in the United States is an immigrant, usually a Hispanic/Asian/Pacific Islander; is male; is 20 to 40 years old; and has fever, right upper quadrant pain, leukocytosis, abnormal serum aminotransferase and alkaline phosphatase levels, and a defect on hepatic imaging study. Roughly 90 percent of patients with liver abscesses are men. The abscess usually is single and is in the right lobe of the liver 80 percent of the time.[51] Most frequently, patients have liver abscess without concurrent colitis. Amebae are seen infrequently in the stool at the time of diagnosis of liver abscess.[3] Liver abscess can manifest acutely as fever and right upper abdominal tenderness and pain or subacutely as prominent weight loss and less frequently fever and abdominal pain. The peripheral white blood cell count is elevated, as is the alkaline phosphatase level, in many patients.

Early evaluation of the hepatobiliary system by ultrasonography or computed tomography (CT) is essential to show the abscess in the liver. The differential diagnosis of the lesion in the liver includes pyogenic abscess, hepatoma, and echinococcal cyst. Aspiration of the abscess occasionally is required to diagnose amebiasis (although amebae are visualized in the pus in only a few cases; if the abscess is pyogenic, the responsible bacteria are seen or cultured). Antibodies to *E. histolytica* are present in the serum of 70 to 90 percent of patients on acute presentation with amebic liver abscess and are useful diagnostically, especially in combination with antigen detection or PCR tests.[41] Unusual extraintestinal manifestations of amebiasis include direct extension of the liver abscess to pleura or pericardium and brain abscess. In a patient who has right upper quadrant pain, ultrasonography, CT, or magnetic resonance imaging (MRI) should be performed to examine the liver and gallbladder.

If a space-filling defect in the liver is observed, the differential diagnosis includes (1) amebiasis (most common in men with a history of travel or residence in a developing country); (2) pyogenic or bacterial abscess (suspected in women, patients with cholecystitis, elderly individuals, individuals with diabetes, and patients with jaundice); (3) echinococcal abscess (an incidental finding

because echinococcal abscess should not cause pain or fever); and (4) cancer. Most patients with amebic liver abscess have detectable circulating antigen in serum and serum anti-amebic antibodies.[36]

In children, abdominal pain is reported infrequently with amebic liver abscess.[35,70] More commonly, high fever, abdominal distention, irritability, and tachypnea are noted. Some children are admitted to the hospital with a fever of unknown origin. Hepatomegaly occurs frequently, but elicitation of hepatic tenderness is not well documented. In one report, four of five children younger than age 5 years died with amebic liver abscesses because the diagnosis was not suspected.[56] Death usually results from rupture of the liver abscess into the peritoneum, thorax, or pericardium but may follow extensive hepatic damage and liver failure.[3,84]

Metastatic Amebiasis

Extra-abdominal amebiasis presumably follows direct extension from liver abscesses, rather than direct dissemination from the intestine.[3,16] Thoracic amebiasis is the most common type of extra-abdominal amebiasis and occurs in less than 10 percent of patients with amebic liver abscess.[16,49] Symptoms depend on the type of involvement. Empyema, bronchohepatic fistulas, or extension of a pleuropulmonary abscess into the pericardium may occur.

Pericardial amebiasis is the next most common form of extraintestinal involvement and may result from rupture of a liver abscess in the left lobe of the liver into the pericardium or through extension of the right-sided pleural amebiasis.[16,28,29,34] It is estimated to occur in 3 percent of patients with hepatic abscesses.[29] It manifests as acute pericarditis with tamponade and, occasionally, as pneumopericardium.[28] Amebic liver abscess in the left lobe also may rupture directly into the left side of the chest.[65]

Cerebral amebic abscesses are seen only in individuals with amebic liver abscess and were found in 8 percent of patients with liver abscess discovered at autopsy in one study.[60] In other studies, lower rates of 0.66 to 4.7 percent of patients with amebic liver abscess having brain abscesses were reported.[48,98] Patients with cerebral amebiasis frequently are so ill from the intestinal, liver, and possibly lung involvement that neurologic signs are not always assessed easily. In 18 patients with proven cerebral amebiasis, initial neurologic examination was normal in 13 and only 1 patient later developed seizures.

Other foci of infection are rare findings, but amebic rectovesical fistula formation and involvement of pharynx, heart, aorta, and scapula have been reported. Cutaneous extension after the adherence of perforated, inflamed bowel to the skin is an extremely painful and rare complication.[16,75] This situation also may arise after invasion of the skin occurs from trophozoites emerging out from the rectum.[69]

DIAGNOSIS

The prevalence of diarrhea due to *E. histolytica* in the first year of life in impoverished children in the developing world may be as high as 10 percent.[71] A heightened suspicion of amebiasis should be present if the patient has been in a developing country as a resident or traveler. The diagnosis of amebiasis should be considered in any child with risk factors who has diarrhea, bloody stools, or stools with mucus; with a hepatic abscess; and/or with right upper quadrant pain, abdominal distention, or tachypnea.[56,70] In a patient with diarrhea, if blood is present in the stool (grossly bloody or occult blood positive), infectious (Shiga toxin–producing *E. coli*, *Salmonella*, *Shigella*, *Campylobacter*, and *E. histolytica*) and noninfectious (inflammatory bowel disease, diverticulosis, arteriovenous malformations, cancer) causes should be considered.

Serologic Tests

Serologic tests for anti-amebic antibodies also are a very useful tool in diagnosis, with sensitivity of 70 to 80 percent early in disease and approaching 100 percent sensitivity on convalescence.[97,100] The combined use of serology and stool antigen detection or PCR analysis offers the best diagnostic approach.

Microscopic Examination of Stool

Before the development of new antigen detection tests and PCR analysis, amebiasis was diagnosed by examining a stool sample through a microscope to determine whether *E. histolytica* cysts were present. This method often requires more than one specimen, however, because the number of cysts in the stool varies greatly. In addition, stool microscopy has limited sensitivity and specificity. The body's own immune system produces macrophage cells that can look like the amebae. Four different amebae—*E. histolytica*, which causes amebiasis, *E. dispar*, which does not cause disease, and *E. moshkovskii* and *E. bangladeshi*, which may cause diarrhea—look identical under a microscope.[22,91,95]

Noninvasive Diagnosis of Extraintestinal Amebiasis

Amebiasis outside the intestine has been even more difficult to diagnose. Clinical manifestations of extraintestinal disease vary widely, and less than 10 percent of individuals with amebic liver abscesses have identifiable *E. histolytica* in their stools. The TechLab *E. histolytica* II test, which differentiates the true pathogen *E. histolytica* from *E. dispar*, was reported to detect Gal/GalNAc lectin in the sera of 22 of 23 (96%) patients with amebic liver abscess tested before treatment with the anti-amebic drug metronidazole and 0 of 70 (0%) controls. After 1 week of treatment with metronidazole, more than 80 percent of patients became serum lectin antigen negative. Detection of *E. histolytica* Gal/GalNAc lectin in the sera using the TechLab *E. histolytica* II kit is sensitive to diagnose hepatic and intestinal amebiasis before the institution of metronidazole treatment.[41] A real-time PCR assay detected *E. histolytica* DNA in 49, 77, and 69 percent of blood, urine, and saliva specimens, respectively, from the amebic liver abscess patients.[40]

Noninvasive diagnostic procedures such as ultrasound, CT, and MRI can detect extracolonic amebiasis in the liver, paracecal masses, brain, and other sites, but they cannot distinguish between abscesses caused by amebae and those caused by bacteria, hampering proper treatment of the condition. Most patients with amebic liver abscess have a single abscess in the right lobe of the liver, although multiple lesions also can occur.[4] Chest radiographs show elevation of the right diaphragm in 56 percent of patients with hepatic abscess.[3] The diagnosis of cerebral amebiasis requires careful neurologic evaluation and radiographic evaluation with either CT or MRI.[16,48,60] In one case, *E. histolytica* DNA was detected by PCR in CNS to make the diagnosis.[98] Because of the risk for perforation, barium studies are relatively contraindicated in patients with amebic colitis.

Biopsy Studies

The colonic and rectal mucosa in amebic colitis usually reveals ulcerations with a diameter of 1 to 10 mm. Amebic trophozoites often are at the periphery of these necrotic areas, which can be sampled through a biopsy specimen taken during sigmoidoscopy or colonoscopy.[45,51] Because of the potential for perforation, colonoscopy should be undertaken with caution.

In patients with amebic liver abscesses, amebic trophozoites are found near the capsule of the abscess. Until more recently, the most accurate diagnostic test involved the examination by microscopy of a sample collected from the abscess tissue by needle aspiration, a procedure that is relatively insensitive, identifying amebic trophozoites only 20 percent of the time. PCR in contrast is a sensitive and specific means to identify *E. histolytica* in liver abscess material.[40]

DIFFERENTIAL DIAGNOSIS

Invasive amebic colitis may resemble ulcerative colitis, Crohn disease of the colon (inflammatory bowel disease), bacillary dysentery, or tuberculous colitis.[11,18,45,93] Stool *E. histolytica* antigen or PCR analysis, colonoscopic examination with biopsies, and serologic examination should be able to differentiate amebic colitis from these diseases. Histologic examination of involved colonic mucosa should differentiate amebic colitis, with its lack of inflammation and rare granulation tissue, from the inflammatory responses seen in ulcerative colitis, bacillary dysentery, and Crohn disease of the colon. Tuberculous colitis and Crohn disease are more likely to show granuloma formation than amebiasis. Ileocecal or small bowel involvement as seen on barium studies would suggest Crohn disease or tuberculosis of the gastrointestinal tract, rather than amebiasis. Tuberculous colitis usually is associated with pulmonary tuberculosis and with a strong reaction to tuberculin skin testing. In some cases, differentiating between invasive amebic colitis and inflammatory bowel disease may be impossible. If a patient with this differential diagnosis is placed on corticosteroids and his or her condition deteriorates, the corticosteroids should be stopped and repeat investigation for amebiasis should be performed.[18,70,75]

Amebic liver abscess must be differentiated from pyogenic abscesses and neoplastic lesions. Detection of *E. histolytica* Gal/GalNAc lectin in the sera using the TechLab *E. histolytica* II kit was helpful in one study to diagnose hepatic and intestinal amebiasis before the institution of metronidazole treatment.[41] Total leukocyte counts and cultures of blood may help to differentiate pyogenic and amebic abscesses. Many children with pyogenic liver abscesses have negative blood cultures, however. Often, amebic and pyogenic liver abscesses show similar features on CT and MRI. Occasionally, nuclear imaging with gallium is helpful because, in contrast to a pyogenic abscess, very few neutrophils are contained within an amebic liver abscess.[88,90] Gallium scanning of an amebic liver abscess may reveal a cold spot, possibly with a bright rim. For an individual with risk factors for amebiasis, several investigators recommend instituting treatment for amebic abscess for 3 or 4 days while serologic, antigen detection, or PCR results are awaited.[40,70] Patients with amebic liver abscess should respond to treatment in this length of time by becoming afebrile. No change in size of the liver or size of the abscess should be noted at this time because resolution of the abscess usually takes 2 months to several years.[4,82,83,94,105]

COMPLICATIONS

Complications of amebiasis may be prevented by early establishment of diagnosis and initiation of treatment with appropriate agents.[48,70] When complications occur, the prognosis generally is worse.

Invasive intestinal amebiasis has been associated most commonly with perforation and peritonitis,* which apparently are an end result of "necrotizing" or "toxic" amebic colitis. In children, perforation may be heralded by the appearance of an acute abdomen or pneumoperitoneum, with rapid progression to death, presumably from sepsis.[8,70,104] Surgical resection and therapy for endotoxic shock improve the prognosis.[104] This complication is not rare and accounts for more than 30 percent of deaths from amebiasis in children.[11,52] Massive intestinal hemorrhage causes approximately 3 percent of deaths from amebiasis. Multiple colonic strictures also can occur and cause obstructive symptoms. Fistulas to other organs or to the skin may develop.

Liver abscesses are an unusual manifestation of amebiasis in children, but their resultant complications account for approximately 40 percent of all deaths from amebiasis.[52] Liver abscess also was found in 13 percent of patients with amebiasis at postmortem examinations. Liver abscess with rupture into the abdomen was present in 8 percent of patients who died with amebiasis, and rupture of a liver abscess into the right pleural space was found in 12 percent.[52] Many patients with amebic liver abscess also have anaerobic bacteria in the abscess fluid.[86]

*References 8, 10, 50, 70, 96, 104.

In cases free of bacterial contamination, the fluid has few inflammatory cells and an acidic pH. Amebic pericarditis or pneumopericardium occurs rarely and is found in only 1 percent of patients whose deaths were caused by amebiasis.[28,29,34,52] The fluid is similar to that found in the pleural space. A cerebral abscess was found in 4 percent of patients with amebiasis who died.[52] It has been reported in fewer than 10 children, only 1 of whom survived.[9,16,48,60] Other complications include infections of the retroperitoneal space, stomach, spleen, esophagus, and duodenum.[60]

TREATMENT

Intestinal Amebiasis

Asymptomatic Intraluminal Amebiasis

Therapy for asymptomatic colonization differs from therapy for invasive infection. Asymptomatic infections may be treated with intraluminal agents, such as paromomycin or diloxanide furoate. Each agent has a high rate of success for eradication of cyst passage.[67,68] Paromomycin is a nonabsorbable aminoglycoside that is active against the cyst and trophozoite stages. High cure rates have been reported with a 7-day oral dose of paromomycin at 25 to 35 mg/kg/day in three divided doses (Table 209-2). Diloxanide furoate (Furamide) is a poorly absorbed agent that is quite active against only intraluminal amebiasis.[64] Cure rates have been greater than 90 percent with a 10-day oral course of diloxanide furoate at 20 mg/kg/day in three divided doses (maximum, 1500 mg/day).[67,68,76]

Acute Amebic Colitis

Nitroimidazoles, particularly metronidazole, are the mainstay of therapy for invasive amebiasis.[39] The oral dosage of metronidazole is 35 to 50 mg/kg/day (maximum, 2250 mg/day) in three divided doses for 7 to 10 days for severe intestinal or extraintestinal amebiasis. Metronidazole is concentrated in the ameba, probably via reduction of its nitro group by ferredoxin or flavodoxin-like electron transport proteins, which maintain a gradient for the entry of the unchanged drug. Metabolic intermediates of metronidazole damage DNA and possibly other macromolecules, and they deprive the organism of reducing equivalents by acting as an electron sink. Nitroimidazoles with longer half-lives (tinidazole, secnidazole, and ornidazole) are better tolerated and allow shorter periods of treatment.[41] For children 3 years of age or older, the oral dosage of tinidazole is 50 mg/kg/day (to a maximum of 2000 mg/day) for 5 days for severe intestinal or extraintestinal amebiasis (see Table 209-2).

Approximately 90 percent of patients who present with mild-to-moderate amebic dysentery have a response to nitroimidazole therapy. In the rare case of fulminant amebic colitis, adding broad-spectrum antibiotics to treat intestinal bacteria that may spill into the peritoneum is prudent; surgical intervention occasionally is required for acute abdomen, gastrointestinal bleeding, or toxic megacolon.[39] Agents such as metronidazole that are active against invasive and extraintestinal amebiasis are well absorbed and do not stay in the lumen long enough to have an effect on intestinal amebiasis. Parasites persist in the intestine in 40 to 60 percent of patients who receive nitroimidazole. Nitroimidazole treatment should be followed with paromomycin or the second-line agent diloxanide furoate to cure luminal infection.[41] Metronidazole and paromomycin should not be given at the same time because the diarrhea that is a common side effect of paromomycin may render assessing the patient's response to therapy difficult.[52-54]

Extraintestinal Amebiasis

Amebic Liver Abscess and Metastatic Amebiasis

Extraintestinal and severe intestinal amebiasis must be treated with the tissue-active agents. Metronidazole 35 to 50 mg/kg/day in three divided doses for 7 to 10 days is preferred because it is effective and relatively free of serious side effects (see Table 209-2).[2,3,64,88,90] It is effective for extraintestinal amebiasis in any location, although amebic brain abscesses usually are not treated successfully with any medications. Most patients with amebic liver abscess respond to metronidazole within 72 hours. For amebic colitis, follow-up therapy with a luminal agent is very important because of the high rates of asymptomatic intestinal colonization in patients with amebic liver abscess.

Therapeutic aspiration of an amebic liver abscess occasionally is required as an adjunct to antiparasitic therapy. Drainage of the abscess should be considered in patients who have no clinical response to drug therapy within 5 to 7 days or patients with a high risk of experiencing rupture of the abscess, as defined by a cavity with

TABLE 209-2 **Pediatric Dosage of Drugs for Amebiasis**

Type of Disease	Drug	Dosage
Asymptomatic colonization	Paromomycin	25-35 mg/kg/day in 3 doses × 7 days
Mild-to-moderate intestinal disease	Metronidazole	35-50 mg/kg/day in 3 doses × 7-10 days
	Tinidazole	50 mg/kg/day (maximum, 2000 mg) × 3 days
Severe intestinal and extraintestinal disease	Metronidazole	35-50 mg/kg/day in 3 doses × 7-10 days
	Tinidazole	50 mg/kg/day (maximum, 2000 mg) × 3 days

a diameter of more than 5 cm or by the presence of lesions in the left lobe.[103] Because many patients with amebic liver abscess also have anaerobic bacteria in the abscess fluid,[86] addition of antibiotics, drainage, or both to the treatment regimen in the absence of a prompt response to nitroimidazole therapy is reasonable. Image-guided percutaneous treatment (needle aspiration or catheter drainage) has replaced surgical intervention as the procedure of choice for reducing the size of an abscess.[103]

PROGNOSIS

Invasive disease develops in 50 million people each year, and 50,000 to 100,000 deaths result.[81,87,88] The case-fatality ratio is between 1 in 500 and 1 in 1000 diagnosed cases. Among patients with illness severe enough to require hospitalization, the case-fatality ratio is higher. One small study in children reported a 9 percent mortality rate and a 27 percent morbidity rate.[70]

Bowel necrosis or perforation is the cause of death from purely intestinal amebiasis, and early surgical intervention can reduce the mortality rate of these complications from 100 to 28 percent.[104] Amebic liver abscess has a case-fatality rate of 10 to 15 percent in combined figures of adults and children.[56,73,84] The mortality rate when pleural involvement is noted is 14 percent.[49,56] Amebic pericarditis has a case-fatality rate of 40 percent.[34] Cerebral amebiasis is fatal if untreated.[98]

FUTURE CONSIDERATIONS

Amebiasis would be prevented by eradicating fecal contamination of food and water. Providing sanitation and safe food and water for all children in developing countries is an important and achievable goal but will require massive societal changes and monetary investments. An effective amebiasis vaccine is a desirable and feasible goal to help the approximately 1 billion people living in unsanitary conditions. The high incidence of amebiasis in community-based developing country studies of infants, who bear the brunt of morbidity and mortality from diarrhea, suggests that an effective vaccine would improve child health.

The fact that humans naturally acquire partial immunity against intestinal infection indicates that barriers to stimulating an effective acquired immune response should not be insurmountable. Aiding vaccine design is the demonstration that several recombinant antigens, including the Gal/GalNAc-specific lectin, provide protection in animal models of amebiasis and that human immunity is linked to intestinal IgA against the lectin.[33,37,39] The high degree of sequence conservation of the Gal/GalNAc-specific lectin suggests that a vaccine could be broadly protective. Finally, the absence of epidemiologically significant animal reservoirs suggests that herd immunity could interrupt fecal-oral transmission in humans. The challenges will be to design vaccines capable of eliciting durable mucosal immunity, to understand the correlates of acquired immunity, and, most important, to enlist the continued support of industrialized nations to combat diarrheal diseases of children in developing countries.

CHAPTER 210

Blastocystis hominis and *Blastocystis* spp. Infection

Peter J. Hotez

Blastocystis hominis and related *Blastocystis* species are among the most common gastrointestinal protozoa of humans, with a worldwide prevalence that may be greater than 50 percent.[27,29] The infection is believed to be more common in low- and middle-income countries. Other *Blastocystis* spp. have been described from numerous other vertebrates and insects.[28] Although new information about the molecular and cell biology of this organism has been acquired in recent years, considerable controversy about its true taxonomy and life cycle remains.[4,27,29,31,32] The pathogenicity of *B. hominis* and its ability to cause gastrointestinal illness in humans are equally controversial.[10,11,13,16,24]

ETIOLOGY AND PATHOGENESIS

Since its discovery in the early part of the 20th century by Alexeieff[1] and then Brumpt,[6] *B. hominis* has been assigned to many different phyla in animal and plant kingdoms. Early on, it was identified by various workers as vegetable material, a yeast, a fungus, or a protozoan. Although the organism was identified as a polymorphic protozoan parasite in 1967, its subphylum status bounced between the Sporozoa and the Sarcodina.[4] Nucleic acid sequencing data now suggest that *B. hominis* does not belong to either category[13,14] but instead probably constitutes its own group (class Blastocystea) more closely related to the stramenopiles, a heterogeneous group of unicellular and multicellular protists that includes slime nets, water molds, and brown algae.[29] Additional molecular taxonomic data suggest that the intraspecific variation among stocks of *B. hominis* is sufficiently different to warrant multiple separate species assignments for the organism.[5,29] There are at least 10 recognized subtypes within the *Blastocystis* genus, with ST1 and ST3 being the most common ones isolated from humans.[26] The difference between the subtypes ultimately may have a bearing on the current controversies surrounding the pathogenicity of the organism and different modes of transmission (i.e., zoonotic and human to human).[29] ST3 is believed to be of human origin, whereas the others may be zoonotically transmitted to humans from a variety of animal sources.[28]

Ultrastructural data gathered from light and electron microscopy on organisms obtained from in vitro culture and from fresh fecal material indicate the existence of at least six different parasite forms. These include cyst forms; ameboid forms; and the so-called granular, avacuolar, vacuolar, and multivacuolar forms.[4,26] The *B. hominis* vacuolar cell is the most distinctive and appears as a thin peripheral band of cytoplasm surrounding a large membrane-enclosed central vacuole.[4] The central vacuole may have a storage function. Although *B. hominis* is thought to have predominantly anaerobic metabolism, structures that look like mitochondria have been identified on transmission electron microscopy. *Blastocystis* mitochondria may function in only lipid biosynthesis and not oxidative phosphorylation.[4,31] Alternatively, what appears to be a *Blastocystis* mitochondrion on electron microscopy actually may be a hydrogenosome.[4]

Several highly speculative life cycles of *B. hominis* have been proposed.[4,14] The infective stage probably is a dormant cyst form that undergoes excystation in response to host gastric acid and intestinal enzymes. Excystation may result in the release of avacuolar forms that can undergo facultative transformation to either an ameboid or a multivacuolar form. The multivacuolar form either may encyst to an infective stage or may coalesce to the vacuolar form.[4] These stages are thought to predominate in the large intestine, although organisms also have been recovered from duodenal aspirates. Which if any of these life cycle stages invades tissue or causes disease is unknown. Acquisition of knowledge in this area has been hampered by lack of a suitable animal model, although infection of gnotobiotic guinea pigs with this organism was reported to result in mild intestinal hyperemia and superficial invasion of *B. hominis* into the mucosa of the cecum. Nonspecific inflammation (infiltration of lymphocytes and plasmocytes) and edema of the colonic mucosa have been seen during sigmoidoscopy with biopsy in some patients.[4] So far, except in a subset of patients with irritable bowel syndrome who reportedly show elevated IgG2 antibody,[12] no serologic antibody response to the organism has been shown.[7] The possibility remains that *B. hominis* is entirely commensal in humans.

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

B. hominis has a worldwide distribution in tropical and temperate regions, with infection rates of 54 percent occurring among some populations.* Developing countries,

*References 2-4, 8, 9, 20, 21, 24, 30.

including Brazil, Egypt, and Indonesia, appear to have a higher prevalence than developed countries.[3,28] High rates of infection also have been reported in individuals with a recent history of travel,[23] with exposure to pets or farm animals,[8] and living in institutionalized settings.[4] In many of these individuals, however, *B. hominis* probably is a commensal parasite. Although *B. hominis* is found commonly in preschool-age and school-age children,[20-22] children overall do not seem to be at increased risk for acquisition of infection.[4] Contaminated water may represent the most common source of *B. hominis* transmission.[28]

Most studies investigating the association between *B. hominis* infection and disease are based primarily on clinical laboratory isolates of the organism in patients exhibiting gastrointestinal symptoms. Common clinical complaints include abdominal discomfort, bloating, cramping, diarrhea, and vomiting.[2] As noted earlier, IgG2 seroconversion to *B. hominis* has been linked to irritable bowel syndrome.[12] Weight loss associated with a protein-losing enteropathy also has been described. Infective arthritis also has been reported.[16] Because *B. hominis* commonly is found in symptomatic and asymptomatic individuals, some investigators have proposed that only very heavy infections result in disease.[17,25] Many of these studies were not controlled, however. Overall, the most common symptoms ascribed to *B. hominis* infection are abdominal pain and diarrhea.[28]

Shlim and colleagues[25] conducted a large prospective controlled study among a population of expatriates and tourists in Katmandu, Nepal, who were at high risk for development of traveler's diarrhea. They concluded that *B. hominis* in high concentrations was not associated with diarrhea and that the presence of higher concentrations of the organism in stool was not associated with more severe symptoms.[25] In a subsequent editorial, several design features were cited that may "weaken the authors' conclusions."[15] At least four other prospective trials have been conducted; one supported *B. hominis* as a cause of diarrhea, one argued against it, and two others were inconclusive.[23] The confusion may be resolved partly by the increasing recognition of separate human subtypes of *Blastocystis*,[5,14] which might lead to improved molecular diagnostic techniques to distinguish pathogenic from nonpathogenic species. This situation is analogous to the morphologically identical species of *Entamoeba* (*Entamoeba histolytica* and *Entamoeba dispar*, only the former of which causes colitis). Some investigators believe that by distinguishing between the different subtypes, at least one or more may be identified as pathogenic, especially among immunocompromised patients.[28]

DIAGNOSIS

Light microscopy of wet preparations of fresh or concentrated stool usually identify *B. hominis*. Staining of preparations with iodine or trichrome also is beneficial. Many laboratories attempt to identify the characteristic vacuolar forms, which may be underrepresented in clinical material.[4] Under these circumstances, the services of an experienced technologist are required to identify the less distinctive fecal cyst form.[29] Organisms also can be recovered from biopsy material obtained during sigmoidoscopy and colonoscopy.

TREATMENT

Given the controversy surrounding the pathogenicity of *B. hominis*, a prudent approach is to refrain from treating asymptomatic immunocompetent individuals.[18] In individuals who have gastrointestinal illness and in whom other pathogens have been excluded, administering a course of antiprotozoal chemotherapy may be reasonable. The results of several drug studies, including three that were placebo controlled, indicate that therapeutic improvements with parasite clearance in symptomatic patients were noted with the use of metronidazole (15 to 30 mg/kg/day for 7 to 10 days), nitazoxanide (200 mg twice daily for children 4 to 11 years old and 100 mg twice daily for children 1 to 3 years old), and trimethoprim-sulfamethoxazole (6 mg/kg trimethoprim and 30 mg/kg sulfamethoxazole daily in two equal doses for 7 days in children; 320 mg trimethoprim and 1600 mg sulfamethoxazole daily in two equal doses for 7 days in adults).[19,28] However, because these drugs are broad spectrum, it is possible that clinical improvement may have been a consequence of treating an unidentified enteric pathogen.[28] To date, the scientific community has been unable to fulfill Koch's postulates for members of the genus *Blastocystis*.[28] Some investigators have reported symptomatic improvement in patients receiving either metronidazole or tinidazole.[4,9] Using an in vitro assay that employed metabolic labeling, researchers found that the drugs emetine, satranidazole, furazolidone, and quinacrine were superior in activity to either metronidazole or tinidazole.[4] The authors caution, however, that the in vitro assay does not take into account the pharmacokinetic properties of the drugs. Furazolidone is available in suspension and may be suitable for pediatric use.[11] Tan[28] recommends metronidazole as a first-line treatment despite some evidence of treatment failures, followed by cotrimoxazole or nitazoxanide as second-line drugs. He recommends treatment if diarrhea is persistent and other pathogens are rigorously excluded.[28] Among the other drugs that have been tried with variable success in patients with *B. hominis* infection are iodoquinol, tinidazole, nitazoxanide, paromomycin, ketoconazole, and ornidazole.[26] Newer studies that examine drug sensitivities of different *Blastocystis* subtypes might help clarify this situation, although currently the status of treating human *Blastocystis* infection remains controversial.[26]

CHAPTER 211

Entamoeba coli Infection

Peter J. Hotez

Until recently, *Entamoeba coli* was considered to be entirely nonpathogenic and was of interest to the clinician only because of its morphologic similarities to *Entamoeba histolytica* that might result in misdiagnosis. In 1991, several case reports from northern Europe appeared, however, that implicated *Entamoeba coli* as a possible cause of infectious diarrhea.[2,5,9] Two cases of diarrhea associated with *Entamoeba coli* have been described in children.[2]

ETIOLOGY AND PATHOGENESIS

Entamoeba coli, similar to other members of the genus *Entamoeba*, has trophozoite and cyst forms. The trophozoite is similar in size to that of *E. histolytica* (15 to 50 μm) but has a more sluggish motility with short pseudopodia.[4] The cytoplasm is described as granular, coarse, or frothy and contains numerous bacteria, yeasts, and other food materials.[4,8] Occasionally, red blood cells are seen in the cytoplasm, but their occurrence is not nearly as common as in pathogenic strains of *E. histolytica*. During passage through the colon, the trophozoite rounds up and synthesizes a chitin-containing cyst wall. *Entamoeba coli* cysts measure 10 to 35 μm and usually contain 8 to 16 nuclei, although occasionally 32 nuclei are seen.

Transmission of *Entamoeba coli* infection occurs through the fecal-oral route in the same manner as *E. histolytica* infection. On cyst ingestion, the total number of excysting trophozoites usually is fewer than eight.[4] The *Entamoeba coli* trophozoites colonize the lumen of the large intestine. Very little is known about the events by which *Entamoeba coli* trophozoites occasionally cause human gastrointestinal illness. Even with a pathogenic *Entamoeba coli* strain, the invasive potential of this organism is presumed not to be nearly as great as that of *E. histolytica* because diarrheal disease in patients infected with *Entamoeba coli* is not associated with dysentery or accompanied by a leukocytosis or elevated serum IgA level.[9]

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Entamoeba coli is worldwide in distribution, although it occurs more commonly in warmer climates, especially in tropical urban slums, and in some populations of homosexual men.[4,6] In 1991, Wahlgren[9] described eight patients from Sweden with mild or persistent diarrhea who harbored *Entamoeba coli*. Before receiving specific antiamebic chemotherapy, all eight patients had their stools examined repeatedly by (1) light microscopy, to exclude other protozoa and helminths; (2) electron microscopy, to exclude the presence of some pathogenic viruses; and (3) aerobic and anaerobic culture, to exclude pathogenic bacteria. These patients typically complained of a long history of loose but not watery stools (without blood or mucus), flatulence, and colicky pain. One patient was a parasitology laboratory technician who had symptoms for more than 15 years. Every patient responded to specific antiamebic chemotherapy.[9] Two children with similar symptoms who also responded to antiamebic chemotherapy subsequently were described in Ireland.[2]

DIAGNOSIS AND TREATMENT

Entamoeba coli sometimes is difficult to distinguish from *E. histolytica*, particularly because the nuclear structures of their trophozoite stages are similar.[3] Some differences exist, however, including the karyosome, which is eccentric in *Entamoeba coli* but central in *E. histolytica*, and the cytoplasm, which is coarse and seldom contains red blood cells in *Entamoeba coli*, in contrast to *E. histolytica*.[3] The differences between the cyst stages of *Entamoeba coli* and *E. histolytica* (and *Entamoeba dispar*) are more apparent. The *Entamoeba coli* cyst typically has two to four times more nuclei than cysts in *E. histolytica*. The *Entamoeba coli* cyst has been reported to become more refractive during fixation so that it often is visualized better in a wet preparation.[4] With use of the polymerase chain reaction assay it is possible to distinguish *Entamoeba coli* from other pathogenic amebas.[7]

Generally, *Entamoeba coli* still is regarded by most investigators as a commensal organism. In patients with persistent diarrhea whose diagnostic fecal evaluation reveals only the presence of *Entamoeba coli*, administering a course of specific antiamebic therapy is reasonable.[1] All of the Swedish patients were reported to respond to a 10-day course of diloxanide furoate in a dose of 500 mg three times daily.[7] Children also may respond to an equivalent pediatric dose of 20 mg/kg/day in three divided doses for 10 days. As of 1994, diloxanide furoate was available in the United States from the Centers for Disease Control and Prevention Drug Service. Alternatively, two children from Ireland (where diloxanide

furoate was unavailable) were treated successfully for *Entamoeba coli*–associated diarrhea with metronidazole.[2]

CHAPTER 212

Giardiasis

Tina Q. Tan

Giardiasis is caused by an infection with the flagellated, binucleated protozoan parasite *Giardia lamblia* (also known as *Giardia duodenalis* or *Giardia intestinalis*). Worldwide, it is one of the most prevalent and important infectious causes of diarrheal illness in humans. Anton van Leeuwenhoek first described the parasite when examining his own stool under a microscope in 1681. Vilem Lambl described the trophozoite in 1859, and Grassi described the cyst in 1879.[70] This flagellated parasite, which belongs to the genus *Giardia*, family *Hexamitidae*, and supergroup *Excavata*,[98] is one of the most ancient eukaryotes and lacks many organelles, including Golgi apparatus, peroxisomes, and mitochondria.[36] In 2003, however, mitochondrial genes were discovered in the organism; and the organism has been shown to possess specialized membrane structures, known as mitosomes, that perform the respiratory chain activities of the inner mitochondrial membrane. This lends support to the theory that *Giardia* organisms have become highly evolved and have lost many ancestral characteristics.* For centuries, *Giardia* organisms were thought to be nonpathogenic, but, over the past 30 years, data have shown that *G. lamblia* can be a pathogen that causes both sporadic and epidemic disease.[28,46]

THE ORGANISM AND ETIOLOGY

This organism has two morphologic forms: the infectious cyst, which is relatively resistant to chemicals and environmental stresses, and the trophozoite, which is responsible for the disease. The trophozoite is pear shaped, with a dorsal convexity and a spiral organelle on its ventral surface. The spiral organelle or sucking disk is the way in which the organism attaches to the epithelial microvillus of the upper small intestine.[80] The trophozoite usually measures 10 to 21 μm in length and 5 to 15 μm in width. It has a complex cytoskeleton that maintains the shape of the parasite and anchors the four pairs of flagella, which emerge ventrally, anterolaterally, posterolaterally, and caudally from the cell body. It also has two diploid oval symmetric nuclei surrounded by nuclear envelopes. These nuclei are each about 1 μm in diameter and are located in the anterior half of the cell, at the right and left sides of the longitudinal axis. They live in the small intestine and divide by binary fission. The cyst form is most commonly seen in stool samples and is oval, measuring 8 to 12 μm in length and 5 to 10 μm in width. It contains two to four nuclei and remnants of organelles. Cysts can remain viable for long periods of time (≥3 months) in cold water and are resistant to killing by iodine and chlorine, but they can be destroyed by heating to 50° C and by desiccation. This form of the parasite is responsible for transmission among susceptible hosts.[2,14,15] There are six species of *Giardia* that have been identified based on the morphologic characteristics of the trophozoite: *Giardia duodenalis*, *Giardia agilis*, *Giardia muris*, *Giardia ardeae*, *Giardia psittaci*, and *Giardia microti*. *G. lamblia*, also called *G. duodenalis*, is the primary pathogenic species in humans and other mammals. All the other species primarily infect animal species and cause no significant disease in humans. The species that infects humans is morphologically indistinguishable from that of other mammals.[2,46] Isoenzyme and genetic analyses indicate that isolates from infected individuals exhibit high levels of genetic diversity and comprise a large number of genotypes, which can be placed in four groups.[16] The

different isolates within groups demonstrate some specificity for infection in various mammals versus humans, but there are no consistent genetic differences between isolates that cause symptomatic versus asymptomatic disease. The genotypes are grouped into two major genetic assemblages—assemblage A and assemblage B—and several minor assemblages—assemblages C, D, E, F, and G—that have very strong host specificities and narrow host ranges. It is believed that humans are infected only with assemblages A and B.[28] Studies have demonstrated that in symptomatic infection there is a strong correlation between isolate assemblage type and severity of infection; however, the infectivity and pathogenicity of *Giardia* genotypes seem to vary depending on the age, clinical and nutritional status, and immune responses of the host.[2,50,75,86]

EPIDEMIOLOGY

Giardia infections are ubiquitous, and outbreaks occur in developed and underdeveloped countries throughout the world. Cross-transmission and infection occur between domestic and wild animals and humans and between humans.[24,94] Transmission involves the fecal-oral, waterborne, and foodborne transmission of cysts; thus, the level of sanitation and a high intradomiciliary/peridomiciliary concentration of domestic animals are directly related to the prevalence of infection.* *Giardia* is one of the most common parasites in the United States, affecting persons of all ages, and is found in 4.2 to 7 percent of specimens submitted to the laboratory for examination.[56] The populations that are affected most frequently include children from birth to 5 years of age, adults 31 to 40 years of age, and backpackers, campers, hunters, and travelers to areas where the disease is endemic.[51,73] Data from the National Giardiasis Surveillance System of the Centers for Disease Control and Prevention estimate that 2.5 million cases occur each year in the United States.[118] Cases per 100,000 population range from 1.4 to 30, with seven states reporting more than 15 cases per 100,000 population. In 2005, Vermont had the highest incidence, with 30 cases per 100,000 population. Cases are more prevalent in males, and rates are highest in children 1 to 4 years of age (children in daycare and their close contacts), followed closely by children 5 to 9 years of age and adults 31 to 39 years of age. Most cases are reported in the early summer through early fall.[118]

Giardia is a frequent cause of diarrhea in daycare centers around the world, with infection rates of 1 to 55 percent.† Most children are symptomatic, and chronic passage of cysts in some preschool-aged children in daycare centers may last for as long as 5 to 6 months after the initial diagnosis. Transmission from these infants and children to adult family members is not an uncommon occurrence; up to 25 percent of the children have *Giardia*-positive stools. The prevalence rates are highest in centers with many non–toilet-trained children and staff who change diapers and prepare food without adequate hand washing. Prevalence rates decline after children are toilet trained.[9] Sexual transmission may occur with both heterosexual and homosexual contact, but male homosexual behavior is an established risk factor for acquiring *G. lamblia* infection and cyst passage rates may be as high as 20 percent.[49,58,63] Other persons at risk include campers, backpackers, hunters, and other travelers to national parks, wilderness areas, and disease-endemic areas because of vertical transmission from animals and ingestion of untreated drinking water.[114] Patients who were infected during travel had longer exposures in countries where the prevalence was high.[54] In addition, many outbreaks have been reported in municipal water supplies that have not been treated with flocculation or filtration. From 1985 to 1994, *Giardia* was responsible for 44 percent of the outbreaks of waterborne diarrheal illness in which a cause could be determined. Sixty-four percent of these outbreaks were associated with unfiltered water. According to a sample survey of 66 reservoir sites in Canada and the United States, 81 percent contained *Giardia* cysts at a concentration of 3 cysts per liter before treatment and 1.7 cysts per liter after treatment.[60,61] Treatment of water with iodine preparations kills most cysts, but the cysts are relatively resistant to chlorination. Swimming pools may be another source of infection when used by diapered infants and developmentally delayed individuals.[84] A less common mode of transmission is through ingestion of contaminated food, in which as few as 10 cysts may be required to establish infection.[72,88]

PATHOGENESIS

Humans are infected by the oral ingestion of as few as 10 to 25 cysts.[88] Excystation occurs in the stomach and small intestine, and the trophozoites are found in large numbers in the upper part of the small intestine, where they closely apply their sucking disks to the mucosa (Fig. 212-1). They may penetrate into the secretory tubules of the mucosa and, at times, are found in the gallbladder and in the biliary drainage. Scanning electron micrographs of the intestinal mucosa (Fig. 212-2) demonstrate the mechanical damage caused by the presence of the organisms on the mucosal surface. The histologic changes seen in the tissues do not always correlate with the presence or absence of symptoms. Biopsy specimens of the small intestine in children and adults show normal histology despite the presence of diarrhea and other symptoms.[22] On the other hand, flattening of the brush border, damage to mucosal epithelial cells, and slight flattening of the villi with increased mitotic index, increased goblet cells, alteration of bile content or duodenal flora, and infiltration with inflammatory cells also may be present.[23,77,89,117] Studies have demonstrated that *Giardia* disrupts tight junctional zona occludens, increases permeability, and induces apoptosis in small intestinal epithelial cells. Disruption of the intestinal epithelial cell brush border and inhibition of brush-border enzymes and trypsin may explain the lactose intolerance that

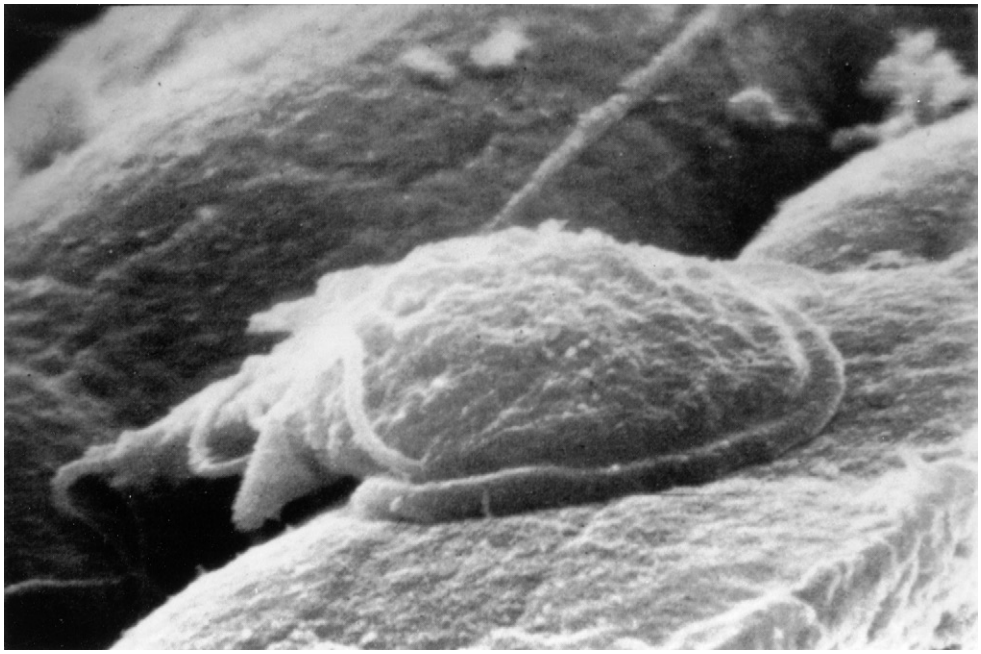

FIGURE 212-1 ■ Trophozoite of *Giardia lamblia* adhering to the intestinal surface.

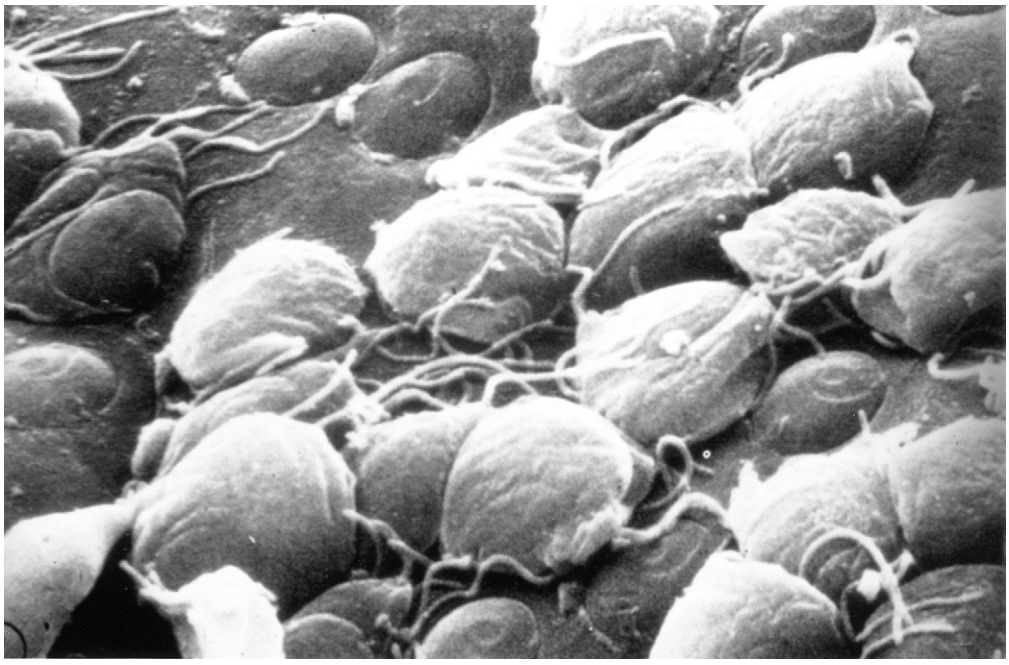

FIGURE 212-2 ■ Scanning electron micrograph of trophozoites of *Giardia lamblia* from an intestinal biopsy. Note the indentations left on the mucosal surface by the parasite's sucking disk.

commonly develops.[12,17] In vivo and in vitro studies have established that *Giardia* causes malabsorption of glucose, sodium, and water and hypersecretion of chloride and reduces disaccharidase activity, owing to shortening of the microvilli in a $CD8^+$ lymphocyte–dependent manner, resulting in loss of epithelial absorptive surface area.[6,11,18,95,96] Disruption of digestion by bile and proteases may produce malabsorption, diarrhea, and resultant malnutrition.

Giardia-infected individuals may have a spectrum of manifestations ranging from asymptomatic carriage to acute or chronic diarrheal disease, the causes of which are not well understood. Hypotheses include (1) the parasite as a physical barrier to absorption, (2) disruption of the brush border with loss of enzymatic activity, (3) elaboration of toxins by the parasite, (4) changes in fat absorption in the small intestine, and (5) activation of cytokines with mucosal inflammation after damage to enterocytes.

Host immunity, both the humoral and cellular components, is important in the variable manifestations of giardiasis and in clearance and protection against reinfection with *Giardia*. Persistence of infection in nude mice suggests a role for T-cell activity.[25,90,102] Humans produce serum immunoglobulin (Ig) G, IgM, IgA, IgE, mast cells, T cells, dendritic cells, and nitric oxide in response to infection.* Studies have shown that IgM and IgG antibody with complement is lethal to *Giardia* trophozoites. In the intestinal lumen, the secretory IgA response appears to play a role in the modulation of infection, as does the migration of infiltrating lymphocytes in the intestinal mucosa. The absence of secretory IgA is associated with the inability to clear *Giardia* infection and is associated with the development of chronic giardiasis in humans.[16,85] Eighty-four percent of human volunteers experienced self-cure in 18.4 days, whereas the remainder became chronically infected.[88] Human milk has been shown to kill the trophozoites of *G. lamblia* by generating toxic lipolytic products.[36,37,87]

Infection may be severe and difficult to eradicate in immunodeficient individuals with antibody deficiencies (e.g., common variable immunodeficiency, X-linked agammaglobulinemia) or in patients with reduced gastric acidity. Giardiasis long has been associated with hypogammaglobulinemia, nodular lymphoid hyperplasia of the small intestine, and chronic diarrhea.[47] Patients with hypogammaglobulinemia, absence of plasma cells in the intestinal lamina propria, cystic fibrosis, protein-calorie malnutrition, and human immunodeficiency virus (or acquired immunodeficiency syndrome) and those who are on immunosuppressive therapy are more likely to develop chronic giardiasis than individuals with X-linked hypogammaglobulinemia, selective IgA deficiency, and Wiskott-Aldrich or Nezelof syndrome.[53,78,99]

CLINICAL MANIFESTATIONS

Infection with *Giardia* can result in asymptomatic infection (5% to 15%), an acute self-limited diarrheal illness (25% to 50%), or chronic diarrhea and malabsorption depending on host susceptibility and pathogen genotype virulence.[6,44,51] The incubation period for giardiasis is 7 to 14 days. Symptoms may vary from mild abdominal discomfort and diarrhea to severe cramping, bloating, and severe, explosive, watery, greasy, foul-smelling diarrhea (Table 212-1).[49] Patients and caretakers describe a constellation of signs and symptoms, including abdominal bloating, flatulence, and frequent foul-smelling diarrhea. Young infants may exhibit anorexia, weight loss, or a malabsorption syndrome that resembles sprue. Symptoms usually last for more than 7 to 10 days and in the majority of cases clear spontaneously. Stooling patterns vary from normal to mushy, foul-smelling diarrhea (Table 212-2). Gross blood, pus, and mucus are usually not present in the stool and signs of inflammatory diarrhea, such as tenesmus and bloody diarrhea, do not occur. *Giardia* infection also may lead to disorders at extraintestinal sites. Extraintestinal symptoms may involve the eyes, joints, and muscles, skin, circulation, and micronutrient deficiencies.[18] A minority of patients will develop persistent, chronic infection that is associated with severe malaise, headache, weight loss, and diffuse abdominal and epigastric discomfort that is exacerbated by eating. Episodes of diarrhea typically alternate with periods of normal bowel movements and may persist over a period of months. Lactose intolerance may develop in 20% to 40% of cases and persist for weeks after the infection has been eradicated.[99,115] Children with symptomatic giardiasis may develop steatorrhea and malabsorption of vitamin A, vitamin B_{12}, protein, D-xylose, and iron.[39,101] Anecdotal reports have attributed a variety of other symptoms, including rash, urticaria, arthralgia, reactive arthritis, constipation, biliary tract disease, and gastric infection to giardiasis, but no firm evidence supports *G. lamblia* as the cause of these symptoms.

Cyst passers may be asymptomatic and may serve as a reservoir of infection for others. This fact is particularly important for food handler and daycare center outbreaks. Severe prolonged illness that requires hospitalization is found in 2 per 100,000 cases, which is similar to that for shigellosis.[62] Hospital admission for young children and pregnant women usually is required because of volume depletion and failure to thrive.[101]

Parasitic infection, including giardiasis, should be considered in the evaluation of the child who fails to thrive and in immunocompromised infants and children who

TABLE 212-1 **Symptoms in Patients with Giardiasis**

Symptom	Frequency (%)
Flatulence	56% to 74%
Anorexia	40% to 64%
Abdominal cramps	55% to 80%
Foul-smelling stool	57% to 72%
Abdominal distention	31%
Bloating	55% to 69%
Nausea	58% to 68%
Malaise	84%
Diarrhea	89%
Belching	30%
Weight loss	48% to 64%
Fever	17% to 28%

have diarrhea or gastrointestinal complaints. It also should be considered in the differential diagnosis of any child who is in daycare or who has traveled outside the United States and has gastrointestinal symptoms.[45,76]

DIAGNOSIS

Obtaining a thorough travel and potential exposure history is important in making the diagnosis of giardiasis. Recent travel to wilderness areas or a national park and travel to developing areas or other endemic areas of the world where fecal-oral hygiene is a problem are important parts of the history in any patient with persistent diarrhea. Demonstration of trophozoites or cysts in the stool on ova and parasite (O&P) examination is the traditional standard of diagnosis.[71] Examination of preserved fecal specimens reveals cysts or trophozoites in most infections. Organisms are excreted in a highly variable pattern; therefore, multiple samples taken on different days are required for detection.[21] A single stool sample misses 20 to 40 percent of the infections, whereas three stool samples miss less than 10 percent of infections.[48]

Commercially available tests to detect antigen by an enzyme-linked immunosorbent assay (ELISA) have been shown to be rapid and highly sensitive and specific but are qualitative and are unable to distinguish between genotypes or detect low levels of infection.[55,113] The ELISA may be particularly useful in screening mass outbreaks and assessing cure. Monoclonal antibodies usually are employed to detect antigen either by an ELISA or immunofluorescence assay. Some of these assays have a sensitivity of 91 to 95 percent and specificities of over 98 percent.[27,68,113] Antigen may be best detected when the stool is preserved in formalin.[27] These tests do not replace microscopic examination of the stool, which is considered to be the standard, because of the possibility of infection with multiple organisms in travelers.

Molecular techniques such as polymerase chain reaction (PCR) are alternative methods that may be used for the specific detection of *Giardia* in the stool. These techniques in combination with restriction fragment length polymorphism or nested PCR may be used to genotype the organisms. The sensitivity of detection by PCR is greater than that of microscopy and is much better for detection of low number of parasites in stool samples.[8] A recent advancement in PCR-based technology for the detection of *G. lamblia* in stool is the use of real-time PCR. This method, using dual-labeled fluorescent probes targeting the β-giardin gene, is sensitive, is rapid, and may be used to detect *G. lamblia* in stool and to differentiate the major genotypes of the organism. It can be adapted to high-throughput detection for the screening of large numbers of samples, especially in outbreak situations.[13,42]

Even with the available diagnostic tests, infections may be missed in some patients; and in cases with a high index of suspicion, the organism may be recovered by duodenal biopsy or duodenal aspiration. Invasive techniques may be an important diagnostic adjunct in immunosuppressed individuals and in those with sprue, for whom histology of the bowel also may be important in planning therapy.

TREATMENT

All patients with either cysts or trophozoites in the stool should be treated. Multiple classes of drugs are available for the treatment of giardiasis, each with different clinical properties and efficacies, as shown in Table 212-3.[5,33,116] The nitroimidazole class of agents includes metronidazole, tinidazole, ornidazole, and secnidazole and is the mainstay of therapy for the treatment of giardiasis. These drugs are administered orally in their inactive probiotic form.[33] Of the nitroimidazoles, metronidazole has been the most extensively studied and widely used worldwide. The mechanism of killing of *Giardia* by the nitroimidazoles involves the utilization of the anaerobic metabolic pathways of the organism. The drug diffuses into the trophozoite, where it is activated and inhibits trophozoite respiration and causes cellular damage by the production of toxic radicals and loss of DNA helical structure, resulting in trophozoite death.[38,107] Of the nitroimidazoles, tinidazole and metronidazole have demonstrated the greatest in vitro activity.[20,41] Metronidazole is considered the drug of choice for treatment, with tinidazole being an alternative.[31,33] Although albendazole has been shown to be curative either in single doses or a 5-day course, it is not approved for use in giardiasis in the United States.[43,120] Quinacrine, which is inexpensive and has excellent efficacy, also is no longer available in the United States.[33] It may cause hemolysis in children with glucose-6-phosphate dehydrogenase deficiency. Furazolidone is an effective alternative and is available in a liquid form. However, it is administered four times a day for 7 to 10 days and is associated with side effects that include rash, nausea, and vomiting. Tinidazole has been shown to eliminate the parasite after single-dose therapy.[31] Another member of the 5-nitromidazoles, secnidazole has been shown to be well tolerated at 30-mg/kg/day (maximum, 2 g) and is an option for therapy.[38] Paromomycin, an aminoglycoside that is not well absorbed, is the only drug that can be used in a pregnant patient. It is not as effective as other medications in eradicating the parasite but may induce clinical improvement. A 3-day course of nitazoxanide has been shown to treat successfully 85 percent of children with diarrhea caused by *Giardia*.[29,91] Although outbreaks in daycare centers are common, treating all children in the daycare center is not efficacious because recurrence rates are high and a chance of a drug reaction always exists. Treatment is reserved for symptomatic children.

Treatment failures and the development of drug resistance have been reported with all of the common agents used to treat *Giardia*, including albendazole, furazolidone, metronidazole, and quinacrine.[5] The prevalence of clinical metronidazole-resistant cases is reported to be up to 20 percent[10,26,106,109,111] with recurrence rates up to 90 percent.[119] Metronidazole-resistant *Giardia* strains have also manifested cross-resistance to tinidazole.[106,109,111] Furazolidone-resistant *Giardia* species can be induced both in vitro and in vivo, and this may induce the organism to become resistant more easily to quinacrine.[69,108,110] *Giardia* resistant to albendazole has been reported to develop rapidly in vitro. Albendazole resistance also

TABLE 212-3 **Drugs for the Treatment of Giardiasis**

Drug	Dose	Efficacy (%)	Side Effects
Metronidazole	15 mg/kg/day orally divided three times a day for 5-10 days (max, 750 mg/day)	80-100	Metallic taste, headache, nausea, vomiting, rash, peripheral neuropathy, neutropenia, disulfiram-like effects
Tinidazole	50 mg/kg, single dose (max, 2 g)	80-96	Metallic taste, nausea, vomiting, headache, rash, peripheral neuropathy, neutropenia, disulfiram-like effects
Ornidazole*	40-50 mg/kg, single dose (max, 2 g)	96-100	Metallic taste, nausea, vomiting, headache, rash, peripheral neuropathy, neutropenia, disulfiram-like effects
Secnidazole	2 g, single dose	90	Nausea, anorexia, abdominal pain
Albendazole†	15 mg/kg/day for 5-7 days (max, 400 mg/day)	94-100	Anorexia, constipation, neutropenia, elevated liver function test results
Furazolidone	6 mg/kg/day orally divided four times a day for 10 days	81-96	Allergic reactions, headache, nausea, vomiting, diarrhea, brown discoloration of urine, hemolysis, disulfiram-like effects
Paromomycin	30 mg/kg/day divided three times a day for 5-10 days (max 1.5 g/day)	55-88	Nausea, vomiting, ototoxicity, nephrotoxicity
Quinacrine*	6 mg/kg/day divided three times a day for 7 days	92-95	Nausea, vomiting, dizziness, headache, yellow/orange skin and mucous membrane discoloration, hemolysis, toxic psychosis
Nitazoxanide	1 to 3 years: 200 mg/day divided twice daily for 3 days 4 to 11 years: 400 mg/day divided twice daily for 3 days ≥12 years: 1000 mg/day divided twice daily for 3 days	85-90	Nausea, abdominal pain, diarrhea, anorexia, flatulence, headache, yellow eyes, discolored urine, increased creatinine and serum glutamic-pyruvic transaminase levels

*No longer produced in United States. Can be obtained from Panorama Pharmacy, Panorama City, Calif.
†Not FDA approved for this indication in the United States.

develops more easily in *Giardia* strains that are furazolidone resistant, giving rise to multidrug-resistant phenotypes.[64,105]

Patients with clinically resistant strains have been treated with longer repeat courses or higher doses of the initial agent[34,74]; however, the most effective means of eradicating these infections seems to be the use of an anti-*Giardia* agent from a different class to avoid potential cross-resistance.[9,19,35] For *Giardia* strains that are phenotypically considered to be multidrug resistant, the administration of anti-*Giardia* drugs in combination is a method that may be used for the successful treatment of the infection.

CHAPTER 213

Dientamoeba fragilis Infections

Damien Stark

Dientamoeba fragilis is a protozoan parasite that may inhabit the human gastrointestinal tract and is associated with gastrointestinal disease.[6,7] Although discovered in 1908, it was not described in the scientific literature until 1918, by Jepps and Dobell.[38] At that time it was considered to be a rare intestinal commensal.[38] In contrast to most other intestinal protozoa, *Dientamoeba* has no known cyst form. In unpreserved feces, the morphologic characteristics of *D. fragilis* do not persist,[39] which most likely accounts for its perceived rarity in some surveys. Studies using appropriate diagnostic methods have found an association between *D. fragilis* infection and acute and chronic gastrointestinal symptoms,[70] which led to its recognition as a pathogenic protozoan.

THE ORGANISM

The trophozoite was classified initially in the genus *Entamoeba*. The similarity of *D. fragilis* to flagellates, however, specifically to *Histomonas meleagridis*, the cause of "blackhead" enterohepatitis in fowl, was noted on careful examination under the light microscope.[24] Later studies using various techniques, including microscopy, immunologic,[26] antigenic,[25] electron microscopy,[4,8,14] and molecular studies,[21,31,63] resulted in the reclassification of *D. fragilis* as a nonflagellate trichomonad.[14,45] Genetic studies confirmed recent evolution with trichomonads,[21,31,63] with two genotypes detected in DNA encoding ribosomal RNA.[40] Genotype 1 seems to predominate in epidemiologic studies.[19,55,80]

D. fragilis infects the mucosal crypts of the large intestine in close proximity to mucosal epithelium from the cecum to the rectum. The organism ranges in size from 3 to 18 μm in diameter, but usually is 7 to 12 μm (Fig. 213-1). The pseudopodia of *D. fragilis* have a delicate, leaflike appearance and serrated margins.[37] This protozoan is seen to move actively in fresh feces, but quickly becomes rounded after standing. *D. fragilis* is easy to isolate and grow in vitro in media containing solid rice starch.[24,52] Cultures should be maintained at 37° to 38° C (98.6° to 100.4° F) because the organism rounds up and stops moving and feeding at lower temperatures. *D. fragilis* thrives in temperatures up to 41° C (105.8° F).[5] This organism feeds on bacteria and starch grains and ingests human red blood cells.

D. fragilis reproduces by binary fission.[4,24] Although the organisms are found most commonly in the binucleate form, approximately 20 percent are in the uninucleate form and a few are multinucleate.[38,43,78,85] Each nucleus contains a large, fragmented (four to eight granules) karyosome surrounded by a clear zone with no peripheral chromatin and a fine nuclear membrane.[24,38,84] Humans seem to be the natural host of *D. fragilis*. *D. fragilis* infection has been reported in a limited number of animals, including nonhuman primates[24,73] and pigs.[13] Multiple attempts to infect other animals have been unsuccessful so far.[6] The atypical morphologic and biologic characteristics of the organism and the absence of an animal model have impeded classification and defining the epidemiology and pathogenicity of *D. fragilis*.[37]

EPIDEMIOLOGY AND TRANSMISSION

Despite the discovery of *D. fragilis* over a century ago, both its life cycle and mode of transmission are poorly defined. The mode of transmission of *D. fragilis* is unknown; however, two mechanisms have been postulated. One hypothesis is that *D. fragilis* is transmitted in the eggs of *Enterobius vermicularis* (pinworm) in a manner similar to the transmission of *H. meleagridis* in the eggs of the avian nematode *Heterakis gallinae*.[11,24,32,77,83] In support of this theory, many investigators have noted a high frequency of concomitant infection with *D. fragilis* and *E. vermicularis*.[11,32,34] Ockert[54] provided the most convincing support for this theory when, by ingesting eggs of *E. vermicularis*, which he had washed with water and exposed to pepsin and hydrochloric acid, he became infected with *E. vermicularis* and *D. fragilis*. Other investigators, noting a high rate of concomitant infection of *D. fragilis* with organisms causing intestinal infections[47,48,51,83] and negative tests for *E. vermicularis*,[20,70,74] suggest fecal-oral transmission.

D. fragilis was thought to be uncommon until improved diagnostic techniques were used for detection, including prompt fixation for preserving the organism[30,33,61] and molecular methods.[68,71,82] The trophozoites of *D. fragilis* have been noted to be quite sensitive to an aerobic environment.[18] They die and disintegrate within 1 hour in an isotonic salt solution at room temperature; when smeared on slides, they round up and become granular within 15 minutes during microscopic examination at room temperature and low humidity.[18]

D. fragilis has been reported worldwide with a prevalence in selected populations of 1.4 to 38 percent.[1] Higher prevalence rates of 19 to 69 percent have been reported in crowded living situations, such as institutions and communal groups,[10,48,50,51,76] extended families in close contact,[74] and in individuals traveling outside the United

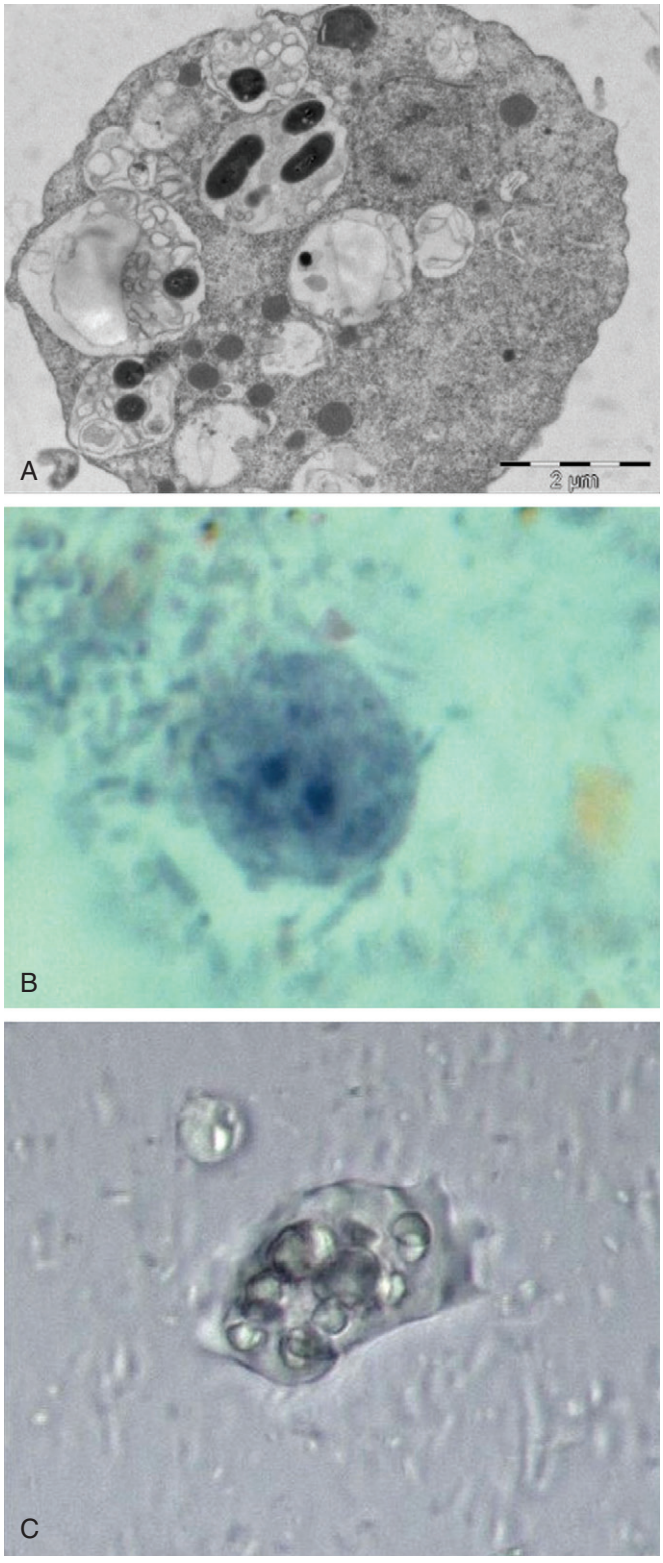

FIGURE 213-1 ■ **A,** *Dientamoeba fragilis* trophozoites on electron micrography. **B,** Light microscopy of trophozoite on modified iron-haematoxylin stain. **C,** Phase contrast microscopy of trophozoite in culture (with ingested rice starch) (See companion Expert Consult website for color version.)

States.[46,58,66,72] A serologic survey in Canada using indirect immunofluorescence techniques detected antibodies to *D. fragilis* in 87 to 100 percent of healthy children 1 to 19 years old,[15] suggesting that infection occurs in most individuals during childhood. Although the antibodies detected in this survey did not absorb when incubated with *Klebsiella pneumoniae* or *Bacteroides vulgatus*, known to contaminate the antigen source of *D. fragilis*, additional studies are needed to confirm the specificity of the assay and to define the seroprevalence in other populations.

CLINICAL MANIFESTATIONS

The clinical presentation of dientamoebiasis ranges from asymptomatic carriage to a variety of symptoms. Gastrointestinal and, less frequently, systemic symptoms have been reported to occur in association with *D. fragilis* in the fecal specimens of children and adults.[2,3] Symptomatic infections occur in 15 to 85 percent of infected individuals.[23,88] Acute watery diarrhea and a chronic recurrent abdominal pain syndrome have been associated with *D. fragilis* in children and adults.[9,12]

Individuals with acute diarrhea also have reported abdominal pain, anorexia, nausea, and vomiting, and, less frequently, fever, weight loss, headache, malaise, fatigue, irritability, and weakness.* The stools have been described as greenish brown, mushy or sticky, with a foul odor and sometimes bloody and with mucus.[41,42] Abdominal tenderness has been found commonly on physical examination[20,41,65] and may mimic appendicitis.[62,77]

When symptomatic, *D. fragilis* infection is associated most frequently with chronic abdominal pain,[20,49,64,65] which may persist for months to years.[35,85] The pain is described commonly as dull, achy, crampy, or colicky and usually is located in the lower abdominal quadrants.[65,85] Complaints of flatulence, fatigue, and alternating diarrhea and constipation are common in individuals with *D. fragilis* infections.[38,65] Laboratory and radiologic studies usually are normal. Eosinophilia, not usually seen with protozoal infections, has been reported in infected children and adults, most commonly in association with chronic symptoms.[20,64,65,75] Eosinophilia has not been observed by others, however.[41] The high prevalence of *D. fragilis* in fecal surveys generally without symptoms and the nonprogressive nature of symptomatic infections should steer clinicians to look for alternative diagnoses in seriously ill children.

DIAGNOSIS

Infection with *D. fragilis* should be considered when abdominal pain, diarrhea, or both persist beyond 1 week. Diagnosis of dientamoebiasis may be problematic if inadequate laboratory methods are used. Investigation for *D. fragilis* infection should include the collection of at least three stool specimens that are immediately placed in a stool preservative such as polyvinyl alcohol stool preservative to retain the morphologic characteristics of the delicate trophozoite.[60,61,79] Diagnosis also can be made by permanent stained smear of a fresh or purged fecal specimen.[11,33,78] Detection of the organism seems not to be compromised by use of "environmentally friendly"

*References 3, 20, 22, 23, 35, 41, 42, 57, 62, 64, 65, 72.

mercury-free stool preservative and stain (EcoFix and EcoStain).[29]

Three fecal specimens properly collected and stained leads to the identification of this intestinal protozoan in 70 to 93 percent of infected individuals.[36,60] Stool specimens should be collected on alternate days because excretion of *D. fragilis* seems to manifest a cyclic pattern.[22] Stool samples should be collected before radiologic studies with barium are done because barium interferes with detection of the protozoa.[28] Other medications interfering with parasite identification include antibiotics, mineral oil, antimalarials, antiprotozoan agents, nonabsorbable diarrheal preparations, and bismuth.[28] These substances may interfere with the detection of parasites for 3 weeks.[28]

After arrival in the laboratory, stool specimens are processed with the use of a formalin-ether sedimentation concentration technique and stained with either iron hematoxylin or trichrome and examined by qualified and experienced individuals for the proper identification of *D. fragilis*.[22,26] Diagnostic characteristics of *D. fragilis* on a permanently stained smear include a high percentage of binucleate trophozoites and nuclei without peripheral chromatin, but with four to eight chromatin granules in a central mass.[21]

Other methods used for the detection of *D. fragilis* include indirect immunofluorescence,[16] xenic culture,[52,59,86] and molecular methods.[55,69,82] Both conventional and real-time polymerase chain reaction assays have been developed and show excellent sensitivity and specificity in contrast to microscopy.[67,68,71] One serologic test has been developed; however, it is not commercially available and the high seroprevalence of *D. fragilis* precludes its use as a diagnostic tool.[10]

TREATMENT

Several agents have been used in the treatment of *D. fragilis* infection. However, it should be noted that most treatment data are based only on a small number of case reports. No large-scale double-blind, randomized placebo-controlled trials testing the efficacy of antimicrobial agents against *D. fragilis* have been undertaken. Presently, one of four drugs is recommended for the treatment of *D. fragilis* infection (Table 213-1): iodoquinol, tetracycline, paromomycin, or metronidazole.[17,44,56,81] However, owing to a paucity of clinical studies, tetracycline and paromomycin are considered investigational by the U.S. Food and Drug Administration.[1,2] Among newer agents, members of the 5-nitroimidazole derivatives secnidazole[28] and ornidazole seem effective in limited studies, and have the advantage of longer half-lives, single dosages, and fewer side effects. Laboratory studies have found that ronidazole,[53] tinidazole,[27,53] and nitazoxanide[53] are active in vitro.

Iodoquinol 650 mg three times daily for 20 days is recommended for adults and 30 to 40 mg/kg/day divided three times daily for children. The tablets should be taken with meals. Side effects include abdominal discomfort, diarrhea, anal irritation and pruritus, headache, and dysesthesias of the hands and feet. Paromomycin 500 mg three times daily for adults and 25 to 35 mg/kg/day in three divided doses in children for 7 days may be more effective than iodoquinol.[87] Adverse reactions to paromomycin include nausea, abdominal cramps, and diarrhea. It is absorbed poorly after oral administration and is no longer available in syrup form in the United States.

Recrudescence or relapse has been reported after one or more 7-day courses of paromomycin in a few treated children.[81] Alternative therapy is tetracycline hydrochloride or metronidazole. Tetracycline is recommended at a dosage of 500 mg four times daily for adults and 40 mg/kg/day in four divided doses for children for 10 days. Tetracycline may cause gastrointestinal and central nervous system symptoms (CNS). It should not be given to children younger than 9 years of age because it may cause discoloration of the teeth. Metronidazole treatment is recommended at a dosage of 500 to 750 mg three times daily for 10 days for adults and 20 to 40 mg/kg/day divided into three doses for children.[3] Treatment with metronidazole may cause gastrointestinal and CNS symptoms. Because of the adverse reactions associated with these drugs, the clinician should evaluate carefully the need for therapy in each case and discuss treatment options with the child's family.

TABLE 213-1 **List of Treatment Options for Dientamoebiasis**

Drug of Choice	Alternative Drugs
Iodoquinol Adults: 650 mg PO three times daily × 20 days Pediatric: 30-40 mg/kg/day (maximum 2 g) PO in three doses × 20 days	**Paromomycin** Adults: 500 mg PO three times daily × 7 days Pediatric: 25-35 mg/kg/day PO in three doses × 7 days **Tetracycline** Adults: 500 mg PO four times daily × 10 days Pediatric: 40 mg/kg/day (maximum 2 g) PO in four doses × 10 days **Metronidazole** Adults: 500-750 mg PO three times daily × 10 days Pediatric: 35-50 mg/kg/day PO in three doses × 10 days

CHAPTER 214

Trichomonas Infections

Joan S. Purcell • Mariam R. Chacko

Trichomonas spp. are found in animals and humans. The most widely studied member of this species is *Trichomonas vaginalis* because it is the trichomonad most relevant to human disease. Donne first described *T. vaginalis* in 1836 as motile microorganisms in the purulent frothy leukorrhea of women with vaginal discharge and genital irritation.[24] Epidemiologic information concerning *Trichomonas* infection is most detailed in the adult population; nonetheless, studies that document the epidemiology of *T. vaginalis* in children and adolescents are available.

MICROBIOLOGY

Trichomonads are acellular flagellated protozoans. The Trichomonadidae family is characterized as mononucleate with an axial organelle that has an undulating membrane. The *Trichomonas* genus includes protozoans that have organelles with three to four anterior flagella and an undulating membrane comprising the posterior flagellum. Five *Trichomonas* spp. infect humans, and three *Trichomonas* spp. infect animals. In humans, the five species of *Trichomonas* include *T. tenax*, *T. ardin delteili*, *T. faecalis*, *T. hominis*, and *T. vaginalis*.[79]

T. vaginalis is the most clinically relevant human trichomonad; the other four species are nonpathogenic. *T. vaginalis* consists of four anterior flagella and a posterior flagellum incorporated into the undulating membrane. *T. vaginalis* can survive but cannot multiply at room temperature. In contrast, *T. hominis* has five anterior flagella and a trailing posterior flagellum, and can survive and multiply at room temperature. Only *T. hominis* can survive in media without serum and in feces for 24 hours.[79]

EPIDEMIOLOGY

Prevalence

Trichomonas infection is found in all age groups, from neonates to adults. Prevalence data concerning *Trichomonas* infection vary widely because it is not as well

documented as other sexually transmitted infections (STIs) because of the absence of screening programs and limitations and variations with diagnostic tests.[33] A vast amount of international prevalence data on *T. vaginalis* STIs stems from research done in clinics and populations in Africa.[5,19] Studies reporting the epidemiology of *T. vaginalis* in children and adolescents are available. Many of the prevalence studies of urogenital trichomoniasis in adolescents and adults are influenced by lack of random sampling, variance in the sensitivity and specificity of the diagnostic tests used, and sample selection, often from sexually transmitted infection (STI) clinics.[33] However the emergence of point-of-care and nucleic acid amplification tests (NAATs) has enhanced epidemiologic information in this field of study. For details on newborns, infants, and premenarcheal children see Chapter 42.

The incidence of trichomonal infections is greater in females than males. Approximately 180 million women worldwide may be infected with *T. vaginalis;* prevalence data depend on the population studied. *T. vaginalis* is seen most commonly in postmenarchal sexually active adolescent girls and women. Up to 700,000 cases of trichomonas infections per year have been reported to the Centers for Disease Control and Prevention (CDC) among women in the United States at their initial physician office visits, and this number has been relatively steady since 1988.[15] The prevalence of *T. vaginalis* urogenital infection varies from 5 to 74 percent in women, with the highest rates reported from STI clinics and other high-risk populations.[33] The 2003 to 2004 National Health and Nutrition Examination Survey, which randomly samples the noninstitutionalized civilian population in the United States, found a 3.6 percent weighted prevalence rate for *T. vaginalis* in sexually active females 14 to 19 years of age by polymerase chain reaction (PCR) testing.[23] In an inner city primary care clinic the prevalence of *T. vaginalis* was 14.4 percent by wet mount and culture in 13- to 19-year-old females.[43] In an urban pediatric emergency department a prevalence rate of *T. vaginalis* by OSOM Trichomonas Rapid enzyme test (Genzyme) was 9.9 percent in 14- to 19-year-old females; 25 percent of the positive tests were among 14- and 15-year-olds.[27] In contrast to females, the prevalence in males is not well studied. In men attending STI clinics, the prevalence of *T. vaginalis* was 22 to 29 percent in sexual contacts of women with trichomoniasis and 6 percent in homosexual men attending the same clinic.[33,44] *T. vaginalis* was found in 58 percent of 85 young black men 16 to 22 years of age who were sexually active, of whom 69 percent previously had an STI.[63]

Risk Factors

Urogenital trichomoniasis is seen more commonly in inner-city patients and patients in the 20- to 30-year-old age group.[53] A large epidemiologic neighborhood study isolated *T. vaginalis* in young adults living in neighborhoods with a higher concentration of blacks, which was mediated by neighborhood poverty. Factors such as immigrant concentration and residential instability were not associated with *T. vaginalis.*[22] Trichomoniasis apparently does not have a seasonal pattern of infection.[53] The rate of *T. vaginalis* infection is increased in black women; women with other STIs, including gonococcal cervicitis; a vaginal pH shift greater than 4.5; pregnancy; menarche; and after menopause.[57,79]

Infection with *T. vaginalis* increases in direct relation to number of sexual partners. An increased number of sexual partners also increases the risk for coinfection with other sexually transmitted organisms, including, but not limited to, *Chlamydia trachomatis*, *Neisseria gonorrhea*, *Mycoplasma hominis*, and human immunodeficiency virus (HIV).[3] Foster care status may be a correlate for higher rates of *T. vaginalis* infection in adolescents. In Wave III of the National Longitudinal Study of Adolescent Health, using a urine PCR enzyme-linked immunosorbent assay (ELISA) test, female participants exposed to foster care were significantly more likely to test positive for *T. vaginalis* infection (2.8%) than their male counterparts in foster care (1.8%).[1] Oral contraceptives diminish the rate of infection with *T. vaginalis* in contrast to an intrauterine device or tubal ligation.[53] The use of nonoxynol-9 spermicidal cream was not related significantly to a decrease in *Trichomonas* infection.[7] In another study of 226 women attending an STI clinic, no association was found among patient age, frequency of coitus, date of most recent coitus, day of menstrual cycle, antibiotic use, contraceptive methods, or symptoms of discharge or pruritus.[57] The risk for *T. vaginalis* is decreased in the wives of circumcised males.[30]

Other risk factors for women may involve a change in the normal vaginal flora, such as overgrowth of *Gardnerella vaginalis*, *Bacteroides*, or *Peptostreptococcus*. These bacteria may serve as sources of nutrients for trichomonads and allow them to thrive. In men, sexual contact with a woman infected with *T. vaginalis*, nongonococcal urethritis, or nongonococcal nonchlamydial urethritis was associated with an increased risk for acquiring infection with *T. vaginalis.*[47] In trichomoniasis, lactobacilli are absent from the vagina. This absence promotes alkalinity of the vaginal pH, enhancing the overgrowth of anaerobes and trichomonads.[72] Another study performed in Africa failed to show a significant role for *Lactobacillus* in patients with *T. vaginalis* infection.[20,55]

TRANSMISSION

Trichomoniasis in newborns through perinatal acquisition with recovery of *T. vaginalis* from urine, vaginal, and respiratory tract specimens has been described. The mode of transmission in children older than 1 year of age is controversial as a history or no history of sexual abuse has been reported. In one study *T. vaginalis* was not identified in any of the asymptomatic healthy control group of prepubertal children.[29] Nonsexual transmission of *T. vaginalis* has been reported in children. In rural India, a point prevalence survey of random samples from preadolescent and adolescent girls complaining of leukorrhea revealed that 76 percent were infected with *T. vaginalis.* Of the girls who were infected, 38 percent were younger than 12 years of age. In this study, poor genital hygiene and underwear use were correlated with a higher incidence of infection. In addition, a significantly higher risk

occurred in girls who washed or bathed in tanks or rivers versus girls who used pipe or well water. In the tropics, nonsexual transmission may account for infection with *T. vaginalis* in preadolescent and adolescent girls.[16] *T. vaginalis* can survive on toilet seats for 1 hour, on wet clothes for 3 hours, in fresh water for 30 minutes, in warm mineral water for 2 or 3 days, and in urine for hours. According to the literature, transmission of *Trichomonas* may occur via fomites (e.g., wash cloths and towels), particularly when people are living together in crowded, confined spaces.[60] For details see Chapter 42.

In summary, *T. vaginalis* conceivably is transmitted to children nonsexually. The likelihood of perinatal transmission is high in infants younger than 1 year of age. A child or an infant younger than 1 year with *T. vaginalis* also may have been sexually abused. In a child older than 1 year of age, suspicion must be high for the probability of sexual abuse. Perinatal transmission and transmission of infection through fomites should not be assumed without an investigation for sexual abuse.

T. vaginalis usually is transmitted sexually in adolescents and adults. In a clinic for patients with sexually transmitted diseases, 60 percent of husbands of women who had chronic, repeated *T. vaginalis* infection were culture-positive for *T. vaginalis*, in contrast to 8 percent in a control group of men attending the same clinic. Large numbers of trichomonads are found in the prostatic secretions of husbands of women with recurrent *T. vaginalis* infection.[77] In a study from the United Kingdom of child and adolescent sexual assault victims, *T. vaginalis* was found in 1 of the 16 girls who were 12 years of age or younger.[38] These data support the concept of sexual transmission of *T. vaginalis*. *T. vaginalis* has been isolated in two males reporting receptive anal intercourse[17] and in a lesbian couple who denied penetrative sex toys or male partners, suggesting transmission may occur through mutual masturbation.[33]

PATHOLOGY AND PATHOGENESIS

As noted previously, five species of *Trichomonas* have been identified in humans; the most clinically important is *T. vaginalis*. *T. vaginalis* is not part of the normal flora, but is found in the human vagina, urethra, and prostate. Inoculation experiments with *T. vaginalis* in the mouth and intestines failed to establish infection in these sites.[79] *T. tenax* is found in the mouth, and *T. hominis*, *T. ardin delteili*, and *T. faecalis* are found in the bowel. *T. tenax* is detected in approximately 5 percent of patients with *T. vaginalis*. *T. tenax*, *T. ardin delteili*, and *T. faecalis* are part of the normal flora and are nonpathogenic. *T. hominis* can infect humans and is associated with gastrointestinal dysentery. The incidence of *T. hominis* in humans is 0.4 to 3.5 percent. *T. hominis* is found only rarely in the stools of patients who concomitantly have *T. vaginalis*.[79]

Virulence factors associated with *T. vaginalis* infection have been defined and include adherence, contact-independent factors, hemolysis, and host macromolecule acquisition. Epithelial cell adherence depends on an intact cytoskeleton and *Trichomonas* protein ligands and proteases, which are necessary to activate adherence molecules.[18,26] Cell contact-independent factors include pH variability and cell-detaching factor, which in vitro inhibit reorganization of cells infected with *T. vaginalis*. *T. vaginalis* produces lactic and acetic acid as by-products of glucose metabolism.[18] These acids lower the pH, which is cytotoxic to epithelial cells. Another metabolic by-product of *T. vaginalis* is cell-detaching factor, which has a cytopathic effect on epithelial cells and increases subepithelial vascularity, producing the clinical sign of "strawberry cervix."[18] The activity of cell-detaching factor is optimal at pH 5.0 or greater. Hemolysis is seen only in the presence of live trichomonads. Cysteine proteases seem to be important for hemolysis because introduction of their inhibitors in vitro eliminates hemolysis by *T. vaginalis*.[12,18]

The addition of metronidazole reduces levels of hemolysis by 50 percent.[18] The hemolytic activity of *T. vaginalis* is temperature-dependent, with maximal hemolysis at 37° C (98.6° F). Hemolysis is inhibited via separation of trichomonads from erythrocytes by a 3-mm filter, suggesting a contact-dependent mechanism.[18] As a parasite, *T. vaginalis* also depends on host macromolecules for nutrition, including plasma proteins and lactoferrin.

The host responds to *T. vaginalis* infection at the cellular level with polymorphonuclear cells and lymphocyte activity. *T. vaginalis* secretes proteases that are chemotactic to polymorphonuclear leukocytes, with resultant phagocytosis and killing of the trichomonad by oxidative mechanisms.[18] *T. vaginalis* secretions are mitogenic to lymphocytes; they enhance phagocytosis by polymorphonuclear cells and may suppress the host immune response if numerous suppressor lymphocytes are activated.

Clinically, women are largely symptomatic, whereas only a few men have symptoms with *T. vaginalis* infection. Estrogen levels in females directly correlate with infection at peak estradiol levels, and symptoms may be influenced by vaginal concentration of estrogen.[26] In an early study of premenarcheal vaginitis in children 3 months to 9 years of age, *T. vaginalis* infection accounted for only 2.8 to 4.4 percent of cases of vaginitis in unestrogenized vaginas in contrast to 50 percent of infections in fully estrogenized vaginas of patients nearing puberty.[28] In asymptomatic males infected with *T. vaginalis*, the prostate gland serves as a reservoir. Men may remain asymptomatic because of the concentration of zinc salts in prostatic fluid, which is cytocidal for trichomonads.[44] In symptomatic males, *T. vaginalis* may be isolated in specimens from urine, urethral discharge, and semen.[39,44]

In the host, trichomonads may serve as a vector for bacteria and viruses, as shown by the high coinfection rate with *T. vaginalis* and human papillomavirus. Although bacteria contaminate trichomonads externally, trichomonads are thought to ingest virus-infected cells and destroy them, with the active virus left intact.[32] *T. vaginalis* has been implicated in pelvic inflammatory disease (PID) via ascension from the vagina to the fallopian tubes. In vitro studies have shown *Escherichia coli* strains, a part of the normal vaginal flora, intimately attached to trichomonads by glycoprotein strands.[40] Trichomonads contaminated with bacteria serve as a vector for the bacteria to produce

pelvic infection on reaching the uterus, fallopian tubes, or peritoneum.[40] Likewise, a more recent study involving Dutch women attending an STI treatment clinic found that 71 percent of the women infected with *T. vaginalis* were coinfected with *M. hominis*. Because of the small sample size, however, whether infection with *T. vaginalis* predisposes females to infection with *M. hominis*, or whether this coinfection reflects the sexual behavior of the individual, remains unclear.[8]

In contrast, vaginal colonization with *Lactobacillus* spp. was thought to inhibit trichomonal invasion by lowering vaginal pH. In a study of 336 African women 15 to 49 years of age, 199 of whom were pregnant, 31 percent were culture-positive for *T. vaginalis* and only 40 percent of the patients tested positive for *Lactobacillus*. Although the rate of *Lactobacillus* colonization in these African women was low, the high rate of *T. vaginalis* infection was not related to the absence of *Lactobacillus*. Trichomonads may not alter the vaginal flora substantially.[55] In women infected with *T. vaginalis* in the lower genital tract, however, the aggressive inflammatory response with resultant punctate hemorrhages allows transmission and infection with HIV-1.[70]

A spectrum of severity of disease exists in patients infected with *T. vaginalis*. Some patients are asymptomatic, whereas others experience severe symptomatic inflammation and discomfort. The virulence of *T. vaginalis* isolates varies; whether this variance is caused by the host response or inherent properties of the parasite is unknown. The Golgi apparatus in *T. vaginalis* is a prominent structure and seems to be a key station in the production of adhesins.[9] Evidence indicates, however, that the dramatic heterogeneity that exists on the surface of the parasite leads to antigenic diversity among different isolates of *T. vaginalis*. In one study, prominent immunogens absent on the surface of *T. vaginalis* isolates led to an enhanced ability of the parasite to cause cytoadherence-dependent killing of HeLa cells in monolayer culture. In addition, only the adherent parasites possessed adhesins, which directly affected cytoadherence and cytotoxicity of the parasites.[2] The cysteine proteases of *T. vaginalis* may be responsible for the cytoadherence, nutrient acquisition, and cytotoxicity of *T. vaginalis*. These proteinases are shed during the life cycle and growth of *T. vaginalis*. One hundred percent of serum samples from women infected with *T. vaginalis*, but none from normal uninfected women, possessed immunoglobulin (Ig)G to numerous trichomonad cysteine proteinases. This serum antiproteinase antibody disappeared after the women received effective therapy for the infection.[3]

Some recent studies provide insight into the relationship between *T. vaginalis* and HIV infection. Potentially biologic synergy is present between *T. vaginalis* and HIV infection, with a 1.5 to 1.7-fold increased risk for HIV acquisition when *T. vaginalis* is present. *T. vaginalis* probably alters the cervicovaginal epithelium by several interacting mechanisms mediated by Toll-like receptors, cytokines, chemokines, and innate immune factors, thereby increasing risk for HIV infection.[76] Women with HIV infection with *T. vaginalis* are found to have a higher prevalence of HIV RNA in vaginal secretions than those without *T. vaginalis* infection. A decrease in mean HIV RNA genital shedding among HIV-infected females also has been noted after *T. vaginalis* treatment and over a 1- to 3-month period.[6] HIV-infected females with *T. vaginalis* alone or with gonorrhea and *Chlamydia* infection also have a 1.9 times higher risk for PID.[6]

IMMUNOLOGY

The interaction between *T. vaginalis* and host immunoglobulins is unclear. In women infected with *T. vaginalis*, specific local antibodies—IgG and IgA—are seen in vaginal secretions. IgA may serve to increase opsonization of the parasite by IgG and result in enhanced phagocytosis. IgG specific for *Trichomonas* cysteine proteases and surface proteins is seen, but it does not help rid the host of infection.[3] *T. vaginalis* synthesizes high-molecular-weight proteins with variable surface expression.[4] Of samples obtained from women infected with *T. vaginalis*, 70 percent of vaginal washes and 80 percent of vaginal mucus samples had IgG to a specific *T. vaginalis* surface protein immunogen with a molecular mass of 230,000 Da (P230). In contrast, no antibody to P230 was detected in uninfected women or in detergent extract depleted of P230, suggesting a highly specific antibody.[4] Clinically, this finding may account for the lack of resistance to repeated *Trichomonas* infections and variable host antibody titers in infected individuals.

CLINICAL MANIFESTATIONS

Trichomonas has been isolated from the tracheal aspirates in preterm neonates with respiratory failure and from nasal secretions in a full-term newborn with suppurative nasal discharge and respiratory distress.[62,74,75] The vagina of an infant may serve as a reservoir of infection that goes unnoticed until the infant is evaluated for fever 5 to 6 weeks after birth. Motile trichomonads and pyuria are seen on examination of the urine. Symptoms resolve after treatment with metronidazole.[64] Premenarcheal girls have diffuse bubbly leukorrhea and pruritus.[51] Vaginitis with a purulent foul-smelling discharge is the most common manifestation of infection with *T. vaginalis* in girls; in some patients, trichomonads may be found in the urine initially, with the development of frank signs of vaginitis 7 to 28 days later.[37]

T. vaginalis causes an infection of the vagina, the urethra, Bartholin's and Skene's glands and the cervix in females. In males it causes an infection of the urethra, urine, semen, Skene's glands, epididymis, and prostate. However, 50 percent of adolescent girls and women and 90 percent of adolescent boys and men infected with *T. vaginalis* are asymptomatic.[73] With control for coinfection with other organisms, *T. vaginalis* infection is associated significantly with purulent discharge, vulvar itching, colpitis macularis (strawberry cervix), and vaginal and vulvar erythema. The sensitivity of the other signs and symptoms of *Trichomonas* vaginitis, including vaginal burning, dysuria, urinary frequency, dyspareunia, frothy

discharge, and cervical friability, is low.[78] Although frothy leukorrhea was associated most frequently with *Trichomonas* infection, 29 percent of the patients with frothy discharge in one study did not have *Trichomonas* infection.[78] Strawberry cervix was pathognomonic of *T. vaginalis* infection, but it was noted in only 2 to 3 percent of patients. Thus, this finding cannot be depended on to establish a clinical diagnosis of *T. vaginalis* vaginitis in most patients.[78] Using an NAAT, *T. vaginalis* has been isolated from the anorectal canal in 8.8 percent of women and 0.9 percent of males who reported anorectal intercourse. The significance of this finding is not completely understood, but it is possible that in women perianal contamination from the vagina occurred.[17]

Trichomonads may ascend the fallopian tubes and, if contaminated with bacteria, can produce PID.[12,40] In HIV-infected girls and women, the risk for developing PID increases significantly with *T. vaginalis* vaginitis.[59] In boys and men, *T. vaginalis* may be manifested as symptomatic urethritis with dysuria secondary to urethral inflammation and discharge. On examination, the discharge often is not visualized. When a discharge is present, it is clear to cloudy, but not grossly purulent. On microscopy, numerous inflammatory cells are seen.[45,49] *T. vaginalis* also may be a cause of chronic nonbacterial prostatitis and may be manifested as chronic prostatitis resistant to standard therapy.[36,49] In addition, *T. vaginalis* has been reported to be an etiologic agent of epididymitis in men, with purulent urethral discharge, scrotal swelling, and enlargement of the epididymis.[21] Although a rare finding, *T. vaginalis* has been reported to infect the median raphe of the penis.[71]

CLINICAL DIAGNOSIS

In girls and women, report of vaginal discharge, the presence of a frothy purulent discharge, vulvar or vaginal erythema, and a strawberry cervix should be suspicious for *Trichomonas* infection. Boys and men tend to be asymptomatic or, if symptomatic, have a purulent urethral discharge and urethral inflammation. If the physician relies on clinical examination alone, 80 percent of infections may be missed.[24,72]

Screening and Diagnosis

No studies have adequately tested screening for asymptomatic females and males. Because of the high prevalence of *Trichomonas* infections in females, testing should be performed in females seeking care for a vaginal discharge. The CDC recommends that screening can be considered in those at high risk for infection (i.e., new or multiple partners, history of STIs, exchange sex for payment, and intravenous drug use).[14] Female foster care attendees also should be considered for routine screening for *T. vaginalis* infections.[31]

Laboratory Tests

Several tests are currently available, including culture, point-of-care tests, and NAAT.

Culture

Culture using Diamond medium is the gold standard for detecting *T. vaginalis* infections.[61] The CDC recommends both culture and vaginal wet mount as acceptable diagnostic testing for *T. vaginalis*. However, cost of and time taken to process this test in the laboratory, storage requirements, and transport requirements of using Diamond media may be prohibitive for routine office use; such settings mainly rely on wet mount testing.[67]

A plastic envelope or pouch method, InPouch (Biomed Diagnostics), is now a standard commercially available method for culture of *T. vaginalis*. This method does not promote the growth of *T. hominis*, a common commensal organism. Vaginal secretions are placed in a liquid with a growth medium that allows the organism to grow and are visualized on direct microscopy. The sensitivity and specificity of the pouch method are 94 percent and 96 percent, respectively; the sensitivity and specificity of wet mount are 58 percent and 100 percent, respectively.[52,61] In contrast to wet-mount examination, the InPouch method also has been found to be significantly more sensitive and specific in one study conducted in young adolescent females (median age, 13.6 years). This underscores the need for accurate testing when using culture-based testing, using InPouch or Diamond medium in cases of sexual abuse.[25] In men, the combination of prostatic massage before collection of the specimen and culture of urethral samples and urinary sediment have a sensitivity of 94 to 98 percent.[47,63]

Point-of-Care Tests

Vaginal microscopy of vaginal secretions continues to be a popular and efficient point-of-care test in the clinical setting. Wet-mount preparations are obtained by swabbing the lateral and anterior vaginal fornices to obtain discharge material with vaginal epithelial cells; the secretions are placed in a tube with normal saline and mounted on a slide as soon as possible to detect motile trichomonads with flagella. These preparations are easy to perform, and the method is cost-effective, but in women its sensitivity is only approximately 60 to 70 percent.[14] The sensitivity of wet-mount preparations decreased from 57 to 22 percent after douching.[24] This method also may be used for urethral specimens in men, but it is insensitive. In addition, the validity of the result depends on the technical skill of the examiner and the rapidity with which the specimen is examined; cooling greatly affects the motility of trichomonads, which may hinder identification.[48] Wet-mount examinations are tests now regulated by the Clinical Laboratory Improvement Amendments, which may be a barrier in performing them in office-based laboratories.

Other point-of-care diagnostic testing for *T. vaginalis* in vaginal secretions in sexually active adolescent and young adult women include an immunochromatographic capillary flow dipstick technology, the OSOM Trichomonas Rapid Test (Genzyme), and a direct nucleic acid probe hybridization test for *T. vaginalis*, *G. vaginalis*, and *Candida* spp., Affirm VP III Microbial Identification System (Becton Dickinson).[11] The results with these tests

can be obtained in 10 minutes and 45 minutes, respectively. Although the sensitivity of both tests on vaginal secretions is greater than 83 percent and the specificity is greater than 97 percent, false-positive test results might occur in low-prevalence populations.[8,14] The direct nucleic acid probe hybridization test has not been validated or approved for use in genital specimens from prepubertal girls or male urethral specimens.[14,31]

Positive attitude toward home testing by adolescent females 14 to 22 years of age predicted high self-test acceptability, and tampon use was associated with increased self-test comfort.[34] Adolescents are capable of performing a point-of-care test with self-collected vaginal swabs with results in 100 percent agreement with swabs and tests conducted by a physician.[35] This is helpful for purposes of clinical research and home-based clinical services.

Nucleic Acid Amplification Tests

NAATs, including PCR assay and APTIMA *T. vaginalis* test (ASR, Gen-Probe), are available through commercial laboratories and frequently combined with tests for bacterial vaginosis, yeast, gonorrhea, and chlamydia. A first-void urine test for *T. vaginalis* by APTIMA is available commercially for females and males. The sensitivity of the PCR assay in detecting *T. vaginalis* in vaginal or endocervical swabs and urine in females and males is 88 percent to 97 percent, and the specificity is 98 percent to 99 percent.[14] The sensitivity of the APTIMA *T. vaginalis* test is 74 percent to 98 percent, and the specificity is 87 percent to 98 percent.[14] However, no data are available in children.[31]

Papanicolaou Smear

Conventional Papanicolaou (Pap) smears can detect trichomonads and have the advantage of being fixed and read at a later time. This method is considered unreliable, however, for the diagnosis of trichomoniasis. *T. vaginalis* does not always appear in its typical pear-shaped morphology after fixation on the slide. Rather, it may appear to be more rounded, similar to a polymorphonuclear leukocyte. Cytopathologic diagnostic criteria for *Trichomonas* infection include the presence of perinuclear halos and a dirty granular background. These features are nonspecific, however, and a similar background and halos can be found with certain other conditions.

The sensitivity of Pap smears for diagnosing *Trichomonas* in culture-proved infection is 56 percent.[46] In a study of 1199 women, *T. vaginalis* infection would have been diagnosed falsely in 37 percent based on Pap smear results. Data show the liquid-based Pap smears to be highly sensitive for *T. vaginalis.* However false-positive test results can occur, and confirmatory testing might be needed in certain circumstances.[14]

Other Diagnostic Tests

Since the availability of NAAT, direct immunofluorescence and enzyme immunoassays are not readily available in the United States for clinical or research purposes. Acridine orange stain is also rarely used in the United States; however, this technique continues to be a useful technique in clinical settings around the world with very basic laboratory resources. The dye stains DNA (yellow-green) and RNA (bright red). *T. vaginalis* stains brick-red with an oval, yellow-green nucleus. The flagella do not stain. Unfixed smears are kept at room temperature for 24 hours; fixed slides may be kept 5 days. Acridine orange stains may permit a rapid, accurate diagnosis of *T. vaginalis* infection. The diagnosis can be confirmed by other diagnostic methods in 93 percent of cases.[56] Acridine orange staining seems to be at least as sensitive as wet-mount examination.[10,65]

TREATMENT

Metronidazole or tinidazole are the treatments of choice for *T. vaginalis* infection and are available for treatment of trichomoniasis in the United States. Worldwide, other drugs used for trichomoniasis include nifuratel, nimorazole, secnidazole, and carnidazole. Despite the availability of these other drugs, metronidazole remains the standard therapy for trichomoniasis. Metronidazole enters the trichomonad via passive diffusion, and its nitro group is reduced to a cytotoxic intermediate that reacts with DNA and causes cell death. Metronidazole is 93 to 95 percent bioavailable, and after oral administration, peak serum levels are attained in 1 to 3 hours and a steady state is attained in 2 to 3 days. Metronidazole is metabolized by the liver, with only 20 percent being protein-bound; the drug is distributed well in the body.[54]

Side effects reported with the use of metronidazole include nausea, vomiting, anorexia, a metallic taste, headache, dizziness, diarrhea, and darkening of the urine. Urticaria, reversible peripheral neuropathy, seizures, and ataxia have been reported with intravenous use. The side effects tend to be dose-related and self-limited.[54] In a study of 1199 women with *T. vaginalis* infection treated with metronidazole, only 4 to 5 percent experienced symptoms of nausea, coated tongue, dryness of the mouth, anorexia, or diarrhea. All symptoms disappeared within a few days of completion of treatment, and in only one case was treatment discontinued because of side effects. In addition, relative and absolute leukopenia was not observed in these subjects. Metronidazole enhances or reactivates the growth of *Candida albicans* in the vagina. Metronidazole may potentiate the actions of anticonvulsants and warfarin. Because a significant disulfiram-like effect is produced when the drug is combined with moderate intake of alcohol, alcohol should be avoided during and for 48 hours after completion of a course of therapy with metronidazole.[54]

In the United States, two treatment regimens are recommended for treatment of *T. vaginalis.* The first is metronidazole 2 g orally in a single dose in adolescents. This regimen is 90 to 95 percent effective.[14] Metronidazole vaginal suppositories are not recommended for the treatment of trichomoniasis in adolescents. The second regimen is tinidazole 2 g orally in a single dose. This regimen is 86 to 100 percent effective. An alternative regimen is metronidazole 500 mg twice daily for 7 days.

Some strains of *T. vaginalis* have reduced susceptibility to metronidazole, with low-level metronidazole-resistant strains reported in 2 to 5 percent of infected cases. Although rare, higher level resistance also has been reported.[58,66,69] Treatment options for metronidazole-resistant cases are limited. If the infection fails to respond to metronidazole, it should be re-treated with tinidazole or metronidazole 500 mg twice daily for 7 days.[14] If treatment failure continues, the patient can be re-treated with 2 g of metronidazole or tinidazole once daily for 5 days.[14]

Treatment of *T. vaginalis* in an HIV-positive adolescent is the same as the standard treatment.[14] However, a randomized clinical trial has demonstrated that the 7-day regimen of metronidazole 500 mg twice daily for 7 days is better than the single-dose regimen in HIV-positive individuals.[41] Metronidazole is a Pregnancy Category B drug. To date, studies have been unable to show consistently an association between metronidazole use during pregnancy and teratogenic effects in infants. In addition, although some data suggest increased risk for having a premature or low-birth-weight infant after undergoing metronidazole treatment, limitations of the studies prevent definitive conclusions regarding risks involved in treatment.[14,42] Treatment during pregnancy may relieve symptoms and prevent pregnancy and perinatal complications. The CDC recommends counseling all pregnant patients on the potential risks and benefits of treatment. Treatment of all symptomatic women is recommended. In asymptomatic women, deferring treatment after 37 weeks of gestation is an option.[14]

Tinidazole is a Pregnancy Category C drug, and its safety in pregnancy has not been evaluated. It is not offered during pregnancy.[14] A breast-fed infant consumes approximately 1 percent of a single 2-g oral dose of metronidazole; infants of mothers who are breast-feeding and who are treated with a single dose of metronidazole for trichomoniasis should be removed from the breast for at least 24 hours after treatment.[14,54] In the case of treatment with tinidazole, breast-feeding can be resumed 3 days after the last dose.

In children with *T. vaginalis* infection of the vulvovaginal area, local therapy with metronidazole is preferred because it has fewer systemic side effects. Cotton-tipped swabs saturated with metronidazole are introduced into the hymen and applied locally. In multifocal infections, genital infections that fail to respond to local therapy, and infections in newborn or infant boys, oral therapy with metronidazole is given (Table 214-1).[50] Before administering oral or intravenous metronidazole to children, the clinician should order baseline hematologic, renal, and liver function tests to monitor changes as therapy continues. Resolution of the signs and symptoms of infection indicates a response to treatment. Eradication of *T. vaginalis* should be confirmed by wet-mount examination or culture (if available) 3 to 5 days after completion of treatment in children.[50]

To date the CDC has not recommended partner treatment for *Trichomonas* infection because of inadequate data to support this approach.[13,14] Despite this, it is not unusual for practitioners to prescribe expedited partner therapy for *T. vaginalis*. As more data emerge to demonstrate a decrease in repeat infection with partner treatment, a national policy on expedited partner therapy for *T. vaginalis* may be reconsidered.[68]

TABLE 214-1 Dosing of Metronidazole in Children

		Metronidazole Administered (mg)	
Age (yr)	Weight (kg)	Orally*	Locally†
0-1	10	150	10
1-6	20.5	250	50
7-12	40	500	150
>12	>40	500-1000	250-500

Modified from Kurnatowska A, Komorowska A. Urogenital trichomoniasis in children. In: Honigberg BM, editor. *Trichomonads parasitic in humans*. New York: Springer-Verlag; 1989, p. 268.
*Oral dose = one third of the total dose administered every 8 hours for 5 to 10 days.
†Local dose = total dose administered intravaginally once daily or half the total dose administered twice daily for 5 to 10 days.

PROGNOSIS

If untreated, *T. vaginalis* can lead to chronic inflammation of the Bartholin and Skene glands in adolescent females and to prostatitis and urethritis with urethral stricture formation in adolescent males.[19] *T. vaginalis* has been associated with adverse pregnancy outcomes, primarily premature rupture of membranes, preterm labor, and low-birth-weight infants.[42] Complete resolution of symptoms plus eradication of *T. vaginalis* usually is noted when treatment is provided promptly in all situations.

CHAPTER 215

Balantidium coli Infection

Peter J. Hotez

Balantidium coli is the largest protozoan parasite and the only ciliate to infect humans.[7,11,18] The organism has a worldwide distribution, but usually it is found in less developed nations of the tropics. Because pigs are the principal animal reservoir, most human infections have been reported in tropical regions where swine have close contact with humans, such as the islands of East Asia and the South Pacific (including the Philippines, Papua New Guinea, and West Irian) and Central and South America (including the Altiplano of Bolivia).[12,13] High prevalence rates of this infection can be found among pig farmers in this region. Balantidiasis occurs in areas where other swine-associated parasitic zoonoses (e.g., taeniasis, trichinellosis, ascariasis) also are prevalent, although infection with *B. coli* occurs rarely. In Iran, where pig raising no longer is permitted, wild boars serve as an animal reservoir.[14] The organism first was described in 1857 by Malmsten, who observed the ciliates from two patients in Sweden.[3]

ETIOLOGY AND PATHOGENESIS

The organism has trophozoite and cyst stages. The trophozoite is a large, pear-shaped organism covered with cilia. Estimates of size range from 50 to 100 μm in length and 40 to 70 μm in width.[7] This enormous protozoan organism typically can be seen by light microscopy using only low-power magnification.[7] Subcellular organelles, such as a cytostome and many large vacuoles containing bacteria and debris, are visualized under higher magnification. Similar to many other ciliates, *B. coli* trophozoites have a macronucleus and a micronucleus. The trophozoites colonize the large intestine, where ultimately they round up and secrete a cyst wall as they pass down the lumen. The cysts measure 50 to 70 μm and also contain a macronucleus and a micronucleus. The cyst stages can survive in the outside environment and are infectious to a wide range of animals, including humans (see later discussion).

Frequently, *B. coli* does not invade human tissues and does not cause clinical disease. Under conditions that are not well understood, however, *B. coli* also has the potential for highly aggressive invasion and destruction of tissue. Whether the invasive potential of *B. coli* results from parasite virulence, compromised host defenses, or some combination of these two factors is unclear. The observation that invasive disease occurs more commonly in debilitated patients and in patients with polyparasitism suggests that host defenses have an important role in limiting tissue destruction by *B. coli*.[1,11]

When parasite invasion occurs, it begins in the colonic mucosa, where ulcerations and secondary microabscesses can result. Extensive tissue damage in the cecum and appendix results in clinical presentations of typhlitis and appendicitis.[4,5,11] Histopathologic examination of these tissues reveals flask-shaped ulcerations and necrosis with an extensive inflammatory infiltrate composed predominantly of polymorphonuclear leukocytes.[4,11] *B. coli* probably creates mucosal ulcerations through the release of histolytic enzymes similar to those described from *Entamoeba histolytica*.[15] Ulcerations can lead to hemorrhage or even colonic perforation. A second type of histopathology has been reported in which patients harboring *B. coli* develop inflammatory polyposis of the rectum and sigmoid colon.[10]

When tissue invasion is extensive, the organism can metastasize to extraintestinal sites and cause hepatic and pulmonary involvement. Polymorphonuclear inflammatory cell infiltration results in abscesses at these sites.[3,5,10] Most patients with metastatic balantidiasis have recognizable defects in host defenses.[10]

EPIDEMIOLOGY

As noted earlier, human balantidiasis has a worldwide distribution, but epidemic foci have been reported in the swine-producing areas of Papua New Guinea, West Irian, Micronesia, the Seychelles Islands, the Philippines, and Central and South America.[3,12,16] Incidence rates can be high among swine farmers and slaughterhouse workers. The potential for development of human *B. coli* infections is thought to be high in areas of poor hygiene where extensive contact occurs between humans and pigs. The major risk factors include close contact between pigs and humans, inadequate sanitation, and subtropical or tropical climates that favor survival of the infective cyst stages.[13] A notorious outbreak of human balantidiasis occurred after a devastating typhoon on the Pacific island of Truk caused widespread contamination of ground and surface water supplies with pig feces.[16] Many other animals, including nonhuman primates, guinea pigs, horses, cattle, and rats, also potentially can serve as reservoir hosts. *B. coli* also colonizes many great apes, including baboons, orangutans, chimpanzees, and gorillas, and clinical balantidiasis has been reported in these primates when they are maintained in captivity.[11] Human epidemics also have been described in institutional settings, especially where crowding mixes with low levels of personal hygiene.[16] In these instances, human-to-human spread has been postulated. Although *B. coli* is not known as an opportunistic pathogen in patients infected with human immunodeficiency virus, at least one case of *B. coli* in this setting has been described.[3]

CLINICAL MANIFESTATIONS

Asymptomatic Infection

Most infections are asymptomatic or cause occasional loose stools. This situation probably accounts for 85 percent of patients harboring *B. coli*.[11] Asymptomatic infection may occur more commonly in children than in adults.[17]

Diarrhea

The next most frequent presentation of *B. coli* infections is in patients who have intermittent diarrhea, abdominal pain, and weight loss.[17] Sometimes, discrete ulcerations can be observed during sigmoidoscopy.[11] Chronic diarrhea has been described in a patient with acquired immunodeficiency syndrome.[2] A subset of patients with balantidiasis subsequently develop invasive disease.

Invasive Colonic Balantidiasis

The hallmark of *Balantidium* colitis is dysentery with bloody and mucous stools, colonic tenderness, leukocytosis, and fever. Sigmoidoscopy and colonoscopy of these patients reveal ulcerations and formation of mucosal granulomas.[1,11,16] Involvement of the large intestine can be diffuse, although in some cases, right-sided colonic lesions predominate. Right-sided colonic lesions can progress to typhlitis or appendicitis.[4,5,11] Transmural involvement of the colon frequently results in intestinal obstruction, hemorrhage, and balantidial peritonitis. Colonic perforation is an ominous complication that is associated with extremely high mortality.[11]

Metastatic and Extraintestinal Balantidiasis

Highly invasive balantidiasis leading to metastatic disease of the mesenteric lymph nodes, liver, and lung is a rare complication that can occur in malnourished, debilitated, and immunocompromised patients. Pulmonary infection with *B. coli* has been described.[13] A case of extraintestinal disease associated with pulmonary hemorrhage and iron deficiency was described recently, possibly as a result of inhalation of pig manure.[9]

DIAGNOSIS

Stools from patients harboring *B. coli* have been described as having a pigpen odor.[17] The examination of wet preparations of fresh or concentrated stools usually reveals cyst and trophozoite forms of *B. coli*. Cilia motility and rapid rotary motion of the trophozoites occasionally can be appreciated under low-power magnification. Because the organism takes up heavy concentrations of dye, stained

preparations typically do not reveal internal structures or even cilia.[7] These large organisms can be confused with helminth ova, especially on stained preparations.[7] As an adjunct to direct fecal examinations, sigmoidoscopy can show ulcerations from which abundant trophozoites may be obtained for diagnosis.[17] Bronchoalveolar wash fluid containing *B. coli* has been reported; it has been suggested that diagnosing such lung infections can be problematic because of the potential to confuse ciliated *B. coli* with ciliated pulmonary epithelial cells.[13]

TREATMENT

For the treatment of intestinal balantidiasis, numerous chemotherapeutic regimens have been tried, usually with some improvement. In many cases, the parasite is not eradicated, however.[11] For children older than 8 years, tetracycline 40 mg/kg/day in four doses for 10 days (maximum, 2 g/day) is the treatment of choice. Tetracycline is considered to be investigational for this condition by the U.S. Food and Drug Administration. Also considered investigational for balantidiasis are the drugs iodoquinol 30-40 mg/kg/day (maximum, 2 g) in three doses for 20 days and metronidazole 35 to 50 mg/kg/day in three doses for 5 days (maximum dosage, 2 g).[6,8] Nitazoxanide also may be effective.[13] Alternative chemotherapeutic agents that have been tried with variable success include paromomycin and chloroquine.[11] Surgical intervention often is required for gastrointestinal invasive complications of *B. coli*, such as typhlitis, appendicitis, and peritonitis.

CHAPTER 216

Cryptosporidiosis

Theresa J. Ochoa • A. Clinton White, Jr.

Cryptosporidium is an important cause of acute diarrhea in normal hosts worldwide, of persistent diarrhea in children in developing countries, and of chronic diarrhea in immunocompromised hosts, including patients with acquired immunodeficiency syndrome (AIDS).[81,119,187,210] These protozoan parasites were identified first in the stomach of mice in 1907[200] and for decades were considered to be veterinary pathogens. The first human cases of cryptosporidiosis were reported in 1976.[134,155] In the early 1980s, large numbers of cases were noted with the emerging epidemic of AIDS.[49] Thereafter, *Cryptosporidium* was identified in animal handlers and children[49,214] and was associated with large waterborne outbreaks of diarrhea.[50,124] Studies have shown that *Cryptosporidium* is a common cause of diarrheal disease in immunocompetent and immunocompromised hosts. Recent studies using more sensitive techniques suggest that it is an underrecognized cause of moderate-to-severe diarrhea in Africa and Asia. *Cryptosporidium* is thought to be second to rotavirus as a cause of diarrhea morbidity worldwide.[149,187]

MICROBIOLOGY

Cryptosporidium spp. are ubiquitous, small (2 to 6 μm), obligate intracellular protozoan parasites that infect the epithelium of the gastrointestinal tract of vertebrates. *Cryptosporidium* was previously classified within the subclass Coccidia, along with *Isospora*, *Cyclospora*, and *Toxoplasma*, but this may soon change.[210] Species names were given according to the animal that they infected.[59] Initial cross-transmission studies revealed that little host specificity exists. Subsequent genetic studies have identified at least 26 accepted species of *Cryptosporidium* and more than 45 *Cryptosporidium* genotypes.[33,116] At least 15 species have been documented to cause human infection.[18,33] Most human infections are caused by separate

species, *C. hominis* and *C. parvum*. *C. hominis* is found only in humans (but can infect gnotobiotic pigs), and *C. parvum* is found in a wide range of animals (particularly cattle and sheep) and in humans. The relative frequency of *C. hominis* and *C. parvum* in humans differs in geographic regions, probably as the result of differences in transmission routes. In European countries, *C. parvum* is found more commonly in human cases than *C. hominis*, although a more recent study in the United Kingdom has shown a comparable rate for both pathogens.[114] In the rest of the world, *C. hominis* is the predominant species in humans.[22,24,216] *C. meleagridis* has been identified in most case series. Humans are less frequently infected with *C. cuniculus*, *C. canis*, *C. felis*, *C. muris*, *C. ubiquitum*, and *C. viatorum*.[23,37,56,57,68-70] Rare infections have been noted with six other species and four other genotypes.[33]

LIFE CYCLE

Cryptosporidium spp. can complete their entire life cycles, including asexual (merogony) and sexual (sporogony) reproductive cycles, within a single host (homoxenous). The life cycle is characterized by six major developmental stages: (1) excystation, or release of infective sporozoites; (2) merogony, or asexual replication in the host; (3) gametogony, or the formation of microgametocytes and macrogametocytes; (4) fertilization, or the union of microgametocytes and macrogametocytes; (5) oocyst formation; and (6) sporogony, or the formation of infectious sporozoites within the oocyst wall (Fig. 216-1).[18,59,156]

The life cycle begins with ingestion of the infectious oocyst. The oocysts are activated in the stomach (temperature and acid) and upper intestines (bicarbonate, bile, and pancreatic enzymes). This allows the organisms to excyst, releasing four infective sporozoites.[156] The motile sporozoites glide over the surface of the epithelium and bind to receptors on the surface of the intestinal epithelium, inducing actin polymerization and protrusion of the intestinal epithelial cell membrane.[156] The membrane surrounds the sporozoite and fuses to form the parasitophorous vacuole, which remains in the microvillus layer on the surface of the epithelium. Inside the parasitophorous vacuole, the parasites undergo asexual reproduction (merogony). They enlarge into trophozoite forms and divide to form type I meronts, which mature and rupture to release the motile merozoites. The merozoites bind to receptors on the epithelial cells and are engulfed by the cells. They then either repeat the process of merogony or undergo sexual differentiation (sporogony).

In the case of sexual differentiation, the merozoites differentiate into the microgametocytes and macrogametocytes. The microgametocyte releases the microgametes, which penetrate the cells infected with macrogametocytes. The macrogametocyte and microgametes fuse to form the zygote form, which then undergoes meiosis to form the oocyst, containing four sporozoites. Two morphologic forms of the oocyst have been described: thin-walled oocysts, which excyst within the same host in a process of self-infection, and thick-walled oocysts, which are shed into the environment.

EPIDEMIOLOGY

Cryptosporidium is distributed worldwide. Infection generally is more common in warm, humid months. Prevalence rates generally are higher in resource-poor countries than in industrialized countries.[119] Older surveys not involving patients with human immunodeficiency virus (HIV) documented oocysts in 1 to 3 percent of specimens from industrialized countries of Europe and North America and in about 10 to 15 percent of specimens from developing countries.[119] Most studies on the prevalence of infection have relied on detection of oocysts in fecal samples using acid-fast stains, which are insensitive. With the development of improved diagnostic techniques, more cases are being identified. Using direct immunofluorescence, *Cryptosporidium* was found in 19 percent of children with diarrhea in Brazil.[164] By antigen assay, 19 percent of children with diarrhea in Tanzania has cryptosporidiosis.[148] With the use of polymerase chain reaction (PCR), *Cryptosporidium* was found in 18 percent of hospitalized patients and schoolchildren in South Africa,[182] in 25 percent of children with diarrhea in Uganda,[199] in 36 percent of children prospectively followed in an urban slum in Brazil,[23] and in 15 percent of children with diarrhea in India[5] Thus, the prevalence may be higher than suggested by earlier stool studies.[187]

In wealthy countries, cryptosporidiosis is an important, but underdiagnosed problem. The number of cases reported in the United States tripled in the early 2000s, in part because of increased use of diagnostic tests. Currently, approximately 8000 cases are reported per year in the United States (incidence of ~3/100,000).[217,218] However, the actual number of cases is estimated to be 100-fold higher because of underdiagnosis and underreporting.[184] In England and Wales, over 4000 cases are reported per year (incidence 8/100,000/yr).[38] In both countries, more cases are detected when laboratories employ routing testing for *Cryptosporidium* in all stools from children and when more sensitive immunologic techniques are used (instead of stool microscopy).[35,129,167]

Cryptosporidium is more frequent in children than in adults. Studies from Peru, Brazil, India, Bangladesh, Guinea-Bissau, and Zimbabwe have documented frequent infections in children during their first 2 years of life.* In a Peruvian birth cohort study of diarrheal disease, the incidence rate of cryptosporidiosis determined by a serologic assay was higher than the rate determined by stool microscopy (0.77 vs. 0.41 infection/child-year of surveillance).[170] Similarly high seroprevalence rates were noted along the U.S.–Mexico border.[112] Young children in daycare centers are at high risk for acquiring infection. Outbreaks of cryptosporidiosis in daycare centers have been reported from numerous countries.[10,45,75,136,205]

Cryptosporidium is a common cause of diarrhea in patients infected with HIV. Cryptosporidiosis occurs in an estimated 10 to 15 percent of patients with AIDS in developed countries and in 30 to 50 percent of patients with AIDS in developing countries.[119] Among patients

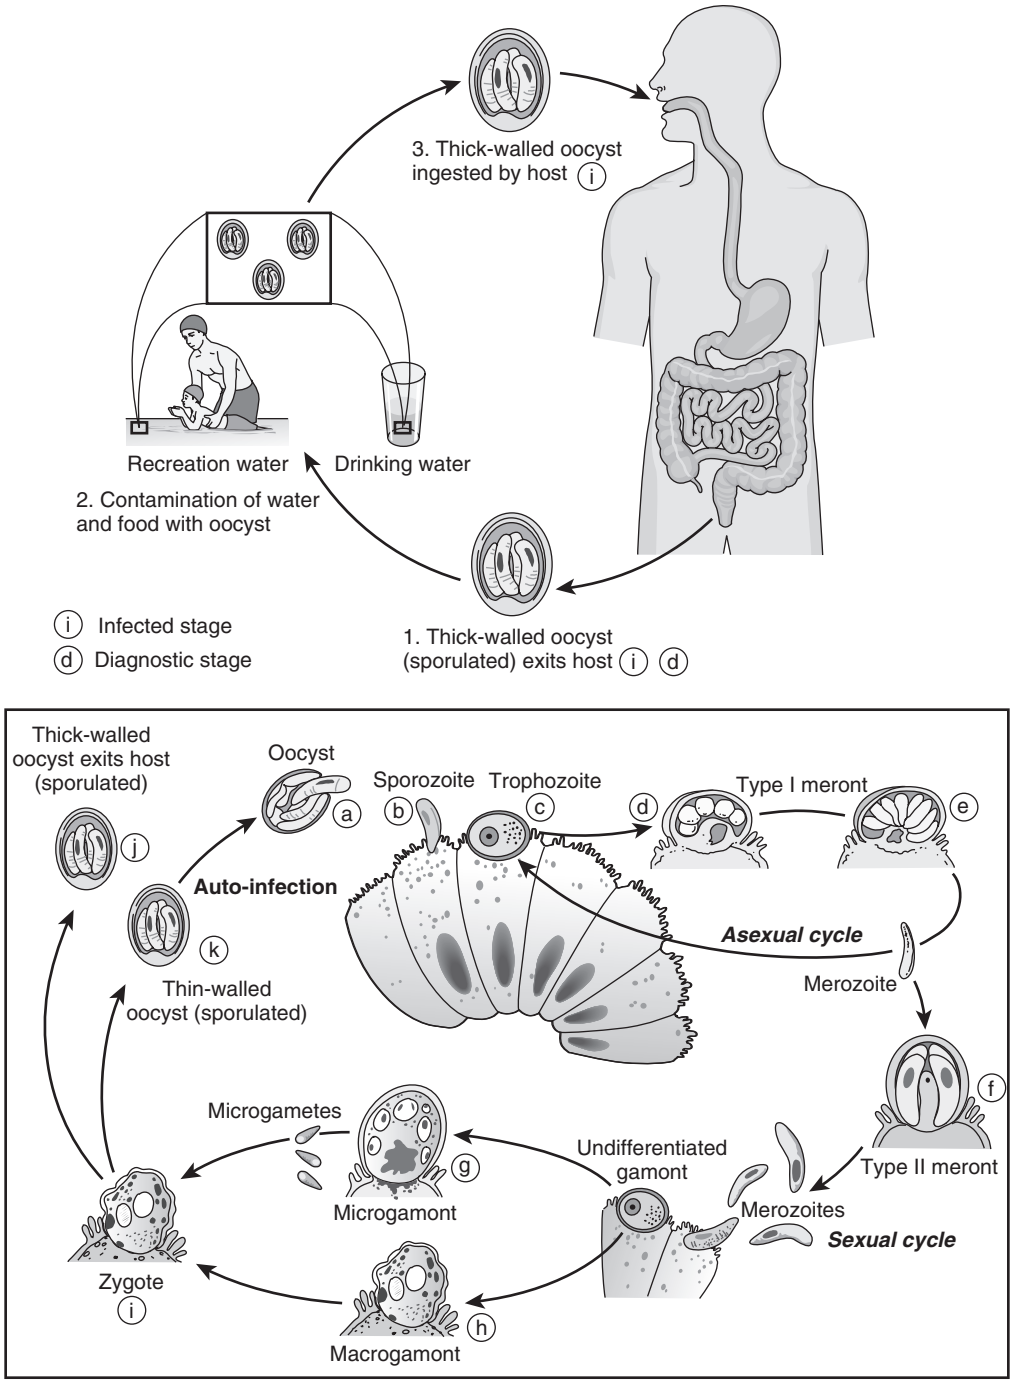

FIGURE 216-1 ■ Life cycle of oocyst. After ingestion, the oocysts (a) release the sporozoite (b), which attach to and are engulfed by the epithelial cell. Inside the parasitophorous vacuole, the organisms enlarge to form trophozoites (c) and divide to form meronts (d, e, and f). After reinvasion, they may differentiate into the sexual forms (microgamont and macrogamont, g and h), which fuse to form the zygote (i). The zygote releases the thin-walled oocysts (k), which cause autoinfection, or thick-walled oocysts (j), which are the infectious form.

with HIV, the infection rate is proportional to the $CD4^+$ cell count. In a longitudinal study of patients with HIV, the infection rate varied from 23 percent of patients with $CD4^+$ cell counts greater than 1000/μL to 46 percent with cell counts less than 100/μL.[168] In recent years, the widespread use of highly active antiretroviral therapy has resulted in the restoration of immune function and a reduction in the incidence of cryptosporidiosis and other opportunistic infections.[111]

Cryptosporidium is a common cause of persistent diarrhea in immunocompetent and immunocompromised children, especially in developing countries.* A study

*References 70, 146, 153, 157, 190, 198, 199.

in West African children investigated episode-specific determinants for the progression of an acute episode of diarrhea to chronic diarrhea; current infection with *C. parvum* was the most significant risk factor.[190] Among 243 children with persistent diarrhea in Uganda, 76 (31%) had *Cryptosporidium*.[198] Of the 243 children, 91 had HIV, of whom 67 (74%) had *Cryptosporidium*. Children with $CD4^+$ cell counts less than 25 percent were more likely to have *Cryptosporidium*.[198]

Cryptosporidiosis also has been noted in other immunodeficient hosts, including patients with primary immunodeficiencies, organ transplantation, cancer, and diabetes.[93] A particularly high prevalence of cryptosporidiosis occurs in patients with X-linked hyper–immunoglobulin (Ig)M syndrome. In two case series of hyper-IgM syndrome, the prevalence of cryptosporidiosis was 24 percent.[85,115] Cryptosporidiosis is also increasingly recognized after solid-organ or stem cell transplantation.[17,108,113]

TRANSMISSION

Humans can acquire *Cryptosporidium* infections through several transmission routes, such as direct contact with infected individuals (person-to-person transmission) or animals (zoonotic transmission) and ingestion of contaminated water (waterborne transmission) and food (foodborne transmission). The relative importance of these transmission routes varies by species and from country to country.[18,38,217] For example, foodborne disease has been noted more frequently in Scandinavia than in other regions.[73] Transmission dynamics are modulated by the low infectious dose, the fact that oocysts are immediately infectious when shed, the resistance of oocysts to chlorination, the stability of oocysts in the environment (especially in water), and the different dynamics of anthroponotic and zoonotic species.

The infectious dose of *Cryptosporidium* is low. In human challenge studies (including *C. hominis*, *C. parvum*, *C. ubiquitum*, and *C. meleagridis*), all demonstrated a low infections dose, but there was considerable variability among isolates, ranging from approximately 1000 oocysts (UCP strain) to 10 oocysts (Texas isolate, *C. hominis*).[39,55,158,159] Because the infectious dose is low, *Cryptosporidium* is transmitted easily from person to person. This route of transmission was recognized initially in outbreaks associated with contact with daycare centers[45,214] and with nosocomial transmission.[61,105,152,183] Secondary transmission within households also is common.[125] During the acute diarrheal illness, large quantities of oocytes are excreted in stool and are highly infectious. Asymptomatic shedding of oocytes may continue for 5 weeks after an acute episode of diarrhea.[192] Contact with an ill individual is a major risk factor for cryptosporidiosis.[18,217] Sexual transmission has been postulated to occur in association with anogenital sex.[86]

Cryptosporidium parasites are well adapted to waterborne transmission.[11,33,91] *Cryptosporidium* oocysts are resistant to environmental conditions; oocysts can remain infectious for at least 6 months if kept moist, but viability decreases rapidly with desiccation.[11,59,156] Oocysts are killed by heat, pasteurization, hydrogen peroxide, ozone, and ultraviolet radiation.[59,102,156] Oocysts are highly resistant to chlorination, however.[106] Surveys have shown that most surface sources of drinking water are contaminated with oocysts before treatment, and even a low-grade contamination has been documented in samples of treated water.

Waterborne outbreaks of cryptosporidiosis have been linked to contaminated drinking water, such as water from artesian wells, surface water, and filtered public drinking water[52,60] and to contaminated recreational water, such as swimming pools, water parks, lakes, rivers, beaches, and fountains.[33,91] The largest documented waterborne outbreak of diarrhea occurred in Milwaukee in 1993, affecting an estimated 400,000 individuals.[124] Many of the waterborne outbreaks, including the outbreak in Milwaukee, have been caused by *C. hominis*. However, both *C. hominis* and *C. parvum* have been implicated in spread by drinking water.[33,38,109] With improvements in filtration, drinking water is less often implicated in cases in the United States and Europe, but *Cryptosporidium* remains the main cause of illness associated with recreational water (e.g., swimming pools, rivers, lakes, fountains).[33,91]

The epidemiology varies considerably by parasite species. Studies in the United Kingdom demonstrated that *C. hominis* is associated with the population of young children, international travel, and recreational water.[38] Incidence peaks in the fall. By contrast, *C. parvum* infection peaked in the spring is associated with animal contact, surface water, and private water supplies. Numerous outbreaks have been attributed to animal contact.[18,38,109] Other species are more frequent in older patients, immunosuppressed hosts (such as AIDS patients), and those with animal contact.[24,56,57,68,171]

Foodborne infections occur less commonly.[217] Outbreaks have been associated with contaminated apple cider, unpasteurized milk, chicken salad, and raw produce. Oocysts are found commonly on vegetables in developing countries.[161] *Cryptosporidium* is associated with international travel and causes approximately 6 percent of traveler's diarrhea.[151]

PATHOLOGY AND PATHOGENESIS

In immunocompetent hosts, the organisms are localized primarily to the distal small intestines and proximal colon. In immunodeficient hosts, the parasites have been identified throughout the gut, in the biliary tract, and in the respiratory tract.[44,77,99] Recent studies employing PCR suggest that respiratory involvement may be underappreciated in children with cryptosporidiosis.[147] Children with persistent cryptosporidiosis may have villous atrophy and a mild increase in lamina propria lymphocytes.[166] Heavier infection is associated with villous atrophy; crypt hyperplasia; marked infiltration with lymphocytes, plasma cells, and neutrophils[44,72,76,77,123]; and with extraintestinal involvement.

Cryptosporidium causes watery diarrhea, malabsorption, and weight loss. These symptoms are thought to result from sodium malabsorption, electrogenic chloride secretion, and increased intestinal permeability.[119] In

vitro studies demonstrated that *Cryptosporidium* infection directly induces defects in intestinal epithelial cell barrier function in vitro.[2,78,175] Cryptosporidiosis also is characterized by defects in intestinal permeability.[76,118,186,219] Increased permeability may result in decreased absorption of fluids and electrolytes and solute fluxes into the gut. Studies in children with cryptosporidiosis have shown a correlation between the severity of disease and altered intestinal permeability.[219] Increased permeability is associated with circulating endotoxin and childhood malnutrition.[145]

Infection of intestinal epithelial cells leads to activation of nuclear factor κB.[135,173,180] Toll-like receptors and MyD88 are key mediators of this pathway.[42,177] The main effect of this activation is to inhibit apoptosis of the infected cells. This signaling pathway leads to modulation of microRNAs and secretion of defensins.[42,156] Increased expression of proinflammatory cytokines and markers of inflammation also occurs, including tumor necrosis factor (TNF)-α and increased expression of proinflammatory CXCL8, CXCL10, and lactoferrin.[103,119,156,163] The chemokines and cytokines recruit inflammatory and immune cells into the intestines. Infection also leads to increased expression of cyclooxygenase-2, production of prostaglandins by the epithelial cells, and production of neuropeptides by the inflammatory cells.[87,110,173] Prostaglandins are thought to mediate decreased sodium absorption and to stimulate chloride secretion. However, prostaglandin inhibitors have not proved to be effective in therapy of human cryptosporidiosis. The neuropeptide substance P correlates with severity of diarrhea in patients with cryptosporidiosis and AIDS and causes many of the defects associated with cryptosporidiosis in a monkey model.[87,173] Octreotide, a substance P antagonist, partially suppresses diarrhea in patients with chronic cryptosporidiosis.[64]

Cryptosporidiosis leads to villous atrophy and crypt hyperplasia.[76,123,166] Increased epithelial cell apoptosis has been shown in cells from tissue cultures and in biopsy specimens from infected intestines.[123] Loss of villous surface area is associated with malabsorption.[44,76,186]

IMMUNOLOGY

Both innate and acquired immunity are important in the defense and clearance of *Cryptosporidium*.[163] Innate responses play a key role in clearance of initial infections.[130] Some host factors have been implicated in innate responses, including mannose-binding lectins, complement, defensins, natural killer cells, and nonspecific inflammatory responses.[27,29,42,51,165]

$CD4^+$ T cells play a key role in the control of cryptosporidiosis, mainly associated with acquired immunity. Among patients with HIV infection, cryptosporidiosis is self-limited in patients with $CD4^+$ cell counts greater than 180/μL, chronic in patients with cell counts less than 100/μL, and fulminant in some patients with cell counts less than 50/μL.[16,62,83,127] Resolution of cryptosporidiosis in patients with AIDS in response to highly active antiretroviral therapy is associated with an influx of $CD4^+$ cells into the intestines.[185] Similarly, Kirkpatrick and colleagues[104] noted an association between MHC class II types (which present antigen to CD4 cells) and susceptibility to cryptosporidiosis.

IFN-γ is an important mediator of the immune clearance of *Cryptosporidium* in murine models.[11,13,14,18] Similarly, lymphocytes from individuals who have recovered from cryptosporidiosis produced IFN-γ after antigen stimulation in vitro.[2] While seropositive volunteers challenged with *C. parvum* express IFNγ in the intestinal mucosa, biopsies from seronegative volunteers in human challenge studies, lymphocytes obtained during active cryptosporidiosis, and stool from children with active cryptosporidiosis lacked IFN-γ expression, despite the fact that all had self-limited disease.[2,5,15] Thus, the role of IFN-γ in human infections is predominantly in acquired immunity and memory responses. CD8 cells may be important in human infection because they produce IFN-γ in response to parasite antigen, MHC class I polymorphisms are associated with risk of infections, and in vitro studies suggest CD8 T cells clear infection in vitro.[6,10-12]

Some IFN-γ–seronegative, normal volunteers were experimentally infected, and in patients with AIDS recovering from cryptosporidiosis, IL-15 was expressed in the intestines in association with IFN-γ-independent control of infection.[160,172] This effect likely is mediated by activation of natural killer cells.[51,130]

The role of antibody in the immune response to cryptosporidiosis is controversial.[163] High levels of serum and fecal antibodies to *C. parvum* have been found in patients with AIDS with chronic cryptosporidiosis and in volunteers challenged with *C. parvum*.[13,46] The presence and timing of antibody correlated with shedding of oocysts, however, rather than with clearance or resistance to infection, and cryptosporidiosis has not been associated with immunoglobulin defects.[93] However, recent studies suggest that maternal antibodies in breast milk may be protective.[107]

Hyper-IgM syndrome, owing to defects in CD40 ligand, is associated with increased frequency and severity of *Cryptosporidium* infection.[3,7] This susceptibility is thought to result from profound defects of antigen-presenting cells, production of IL-12 and TNF-α, and defective stimulation of interferon-γ production.[4] Other primary immunodeficiencies associated with cryptosporidiosis include CD4 cell deficiency, deficient major histocompatibility class (MHC) II, and combined immunodeficiencies.[93,131,215]

CLINICAL MANIFESTATIONS

The clinical spectrum of disease caused by *Cryptosporidium* is broad and depends on the immunologic status of the host, prior exposure, and parasite species (Table 216-1). Symptoms of cryptosporidiosis develop after a prepatent period, during which the parasites invade the intestinal epithelium and proliferate. The prepatent period, determined from point-source exposures and human challenge studies, is approximately 1 week (range 1 to 30 days).[34,124] However, this varies considerably with parasite strain and intensity of exposure. Regardless of the immunologic status of the patient, diarrhea is the most common manifestation of cryptosporidiosis.

TABLE 216-1 **Clinical Manifestation of Cryptosporidiosis**

Host	Clinical Manifestations	Comments
Normal host	Acute watery diarrhea	Relapses are common Persistent diarrhea is common
Children in developing countries	Acute watery diarrhea	Diarrhea more severe in children with malnutrition
	Persistent diarrhea	Persistent diarrhea affects nutritional status, growth, and intellectual function
Immunocompromised host	Acute watery diarrhea	Transient, self-limited, similar to normal host
	Relapsing diarrhea	Very common
	Persistent or chronic diarrhea	Usually found in patients with low CD4 or malnutrition
	Cholera-like illness	Voluminous watery diarrhea, only with very low CD4
	Extraintestinal involvement	Respiratory tract, biliary tract, and pancreas

Children present with an acute diarrheal syndrome characterized by watery diarrhea, cramps, and abdominal pain.[36,119,210] Other, less common clinical findings include fever, flatulence, nausea, vomiting, shortness of breath, and cough. The stools are occasionally described as foul-smelling, bulky stools, or with mucus, but rarely contain blood and fecal leukocytes. Respiratory symptoms are not uncommon, and lung involvement has been noted frequently.[147] In immunocompetent patients, the onset of diarrhea is often abrupt, and the illness usually is self-limited. Recurrent symptoms develop in 40 percent of cases after initial resolution. Relapses may occur after a diarrhea-free period of several days to weeks.[124,125,153] Forty-five percent of cases develop diarrhea lasting more than 14 days.[154,190]

Cryptosporidium is one of the most common causes of prolonged and persistent diarrhea in developing countries, causing about one third of cases.* Children with persistent diarrhea, especially if caused by *Cryptosporidium*, are at high risk for developing additional gastrointestinal infections after the initial illness, weight loss, and premature death.[3,7,117,143,144] Persistent diarrhea in children seriously affects nutritional status, growth, and intellectual function.[14,80] A long-term follow-up study of children with onset of cryptosporidiosis before 1 year of age suggests an association with poorer physical fitness and poorer cognitive development that persists for years.[80] In a second study, long-term effects of early childhood malnutrition were noted, but no significant association with *Cryptosporidium* in contrast to other pathogens was found.[14]

Cryptosporidiosis is more severe in children with malnutrition, and malnourished children tend to have a protracted course and shed oocysts longer.[142,144,145,181] They often require hospitalization, and their diseases may have a fatal outcome.[8,47,183] Prospective cohort studies of children followed from birth have shown significant differences in nutritional status before acquisition of *Cryptosporidium* infection.[3,40,142] In addition, the onset of cryptosporidiosis is associated with growth faltering. Older children eventually recovered and experienced catch-up growth, but children infected before 1 year of age often never recovered.[3,40,142] Asymptomatic infection can lead to malnutrition even without diarrhea.[14,41] *Cryptosporidium* infection causes acute malnutrition, and the long-term consequences of this interaction are likely to be worse in children infected in infancy or with prior malnutrition.

The clinical manifestations also vary somewhat by parasite species. In general, *C. hominis* causes more severe disease than other species. Cama and colleagues[23] noted more nausea, vomiting, and malaise with *C. hominis* than with zoonotic species. Hunter and colleagues[92a,93] noted that *C. hominis* was more strongly associated with extraintestinal sequelae (e.g., joint pain, eye pain, fatigue).[34,92a]

The clinical manifestations of cryptosporidiosis in patients with HIV vary. Four distinct gastrointestinal syndromes have been described in HIV-infected patients: (1) transient, self-limited diarrhea, similar to diarrhea in normal hosts, usually in patients with $CD4^+$ cell counts greater than 150/μL counts; (2) voluminous watery diarrhea or cholera-like illness that requires rehydration, seen in a few cases, usually in patients with CD4+ cell counts less than 50/μL; (3) relapsing diarrhea; and (4) a chronic diarrheal illness resulting in wasting, usually in patients with CD4+ cell counts less than 150/μL.[16,83,123,127,198] The severity and duration of illness in both AIDS patients and other patients with immunodeficiencies generally depend on the degree of immunodeficiency.

In immunocompromised patients, extraintestinal involvement may occur in the respiratory tract, biliary tract, and pancreas.[43,83,122,137,203] Respiratory tract involvement often is asymptomatic, but may cause cough, shortness of breath, wheezing, croup, and hoarseness. *Cryptosporidium* has been reported as a cause of laryngobronchitis in children.[82] Biliary tract involvement in cryptosporidiosis has been limited to patients with profound immunodeficiency.[83,203] Patients may have acalculous cholecystitis or cholangitis and, less frequently, sclerosing cholangitis or hepatitis.[83,194,203] Pancreatitis is an uncommon finding, but it has been reported in adults and children infected with HIV.[84,122,140] Concomitant infection with cytomegalovirus can occur and frequently is associated with irregularities of the intrahepatic duct.[12,90,97]

DIAGNOSIS

Many laboratories do not test for *Cryptosporidium* unless the tests are specifically requested (Table 216-2). *Cryptosporidium* infection usually is diagnosed by microscopic examination of stools. Fresh, preserved, and frozen stools can be used for testing, but preservatives may interfere with some assays.[32,36,189] Numerous concentration

*References 100, 117, 146, 153, 157, 190.

TABLE 216-2 **Diagnosis of *Cryptosporidium* Infection**

Test Type	Method	Comments
Microscopic examination of stools	Modified acid-fast stain of stools	Inexpensive and widely available diagnostic test
	Fluorescent stains (auramine O, auramine-rhodamine)	Faster than other acid-fast stains and may improve sensitivity
	Immunofluorescent assays (IFA)	More sensitive than acid-fast staining but also more expensive
Antigen-detection assays	Enzyme immunoassay (EIA), and immunochromatographic tests: direct and indirect immunofluorescence assay (DFA and IIF)	Good sensitivity (66%-100%) and excellent specificity (93%-100%), but occasional lots associated with false positive tests
Molecular methods	Polymerase chain reaction (PCR)	Increased sensitivity in contrast to microscopic or antigen-detection studies

methods have been attempted to improve the yield, but formalin-ethyl acetate concentration is the most widely used.[32,189] The oocysts are small, 4 to 6 μm, and similar in size and shape to yeast forms, and stains that are used routinely to detect other intestinal parasites (i.e., iodine, trichrome, and iron hematoxylin) do not detect *Cryptosporidium*. The method most commonly used by clinical laboratories to detect *Cryptosporidium* oocysts in stools has been the modified acid-fast stain.[35,167] Oocysts stain pink or red, whereas yeast cells and fecal debris stain green or blue (Fig. 216-2).[32,36,289] The sensitivity of stool examination with acid-fast staining is poor, requiring an oocyst concentration of greater than 500,000/mL in formed stools,[207] with fewer cases detected than with other methods.[36] Fluorescent stains (e.g., auramine O, auramine-rhodamine) can be read more quickly than other acid-fast stains and may have improved sensitivity, but positive results require confirmation by a second method.[36,101,189] Immunofluorescent assays are more sensitive than other microscopic methods.[36,65,101]

Antigen-detection assays are being used increasingly for diagnosis. Commercial kits for *Cryptosporidium* are available in enzyme-linked immunosorbent assay (ELISA) and immunochromatographic formats. The ELISA kits for *Cryptosporidium* have good sensitivity (66% to 100%) and excellent specificity (93% to 100%).[36,65,66,189] The sensitivity has been poor in some studies, however, and pseudo-outbreaks from false-positive results have been reported.[30,54] Commercial ELISA kits also may test for *Giardia* and *Entamoeba* antigens. Immunochromatographic tests are rapid tests for *Cryptosporidium* and *Giardia* antigen.[66,95] The sensitivity is less than with other assays, and results are available in minutes.[66,95] The specificity was initially reported to be excellent, but a recent study from Minnesota suggested a poor positive predictive value.[66,95,174] Antigen assays as a group have the advantage of not requiring skills in microscopic identification of organisms.

Molecular methods such as PCR for *C. parvum* DNA also have been employed to detect organisms. They have increased sensitivity in contrast to microscopic or antigen-detection studies of stool.[5,131,151,189,195] In one study of children with primary immunodeficiencies, PCR was able to detect significantly more cases of biliary cryptosporidiosis than were detected by stool studies.[131] In general, the number of cases detected increases significantly with molecular methods. Multiplex assays, including for a wide range of enteric pathogens, are in development.[120] A multiplex assay for enteric pathogens using polymerase amplification and detection with probes attached to beads was recently approved in the United States.[193]

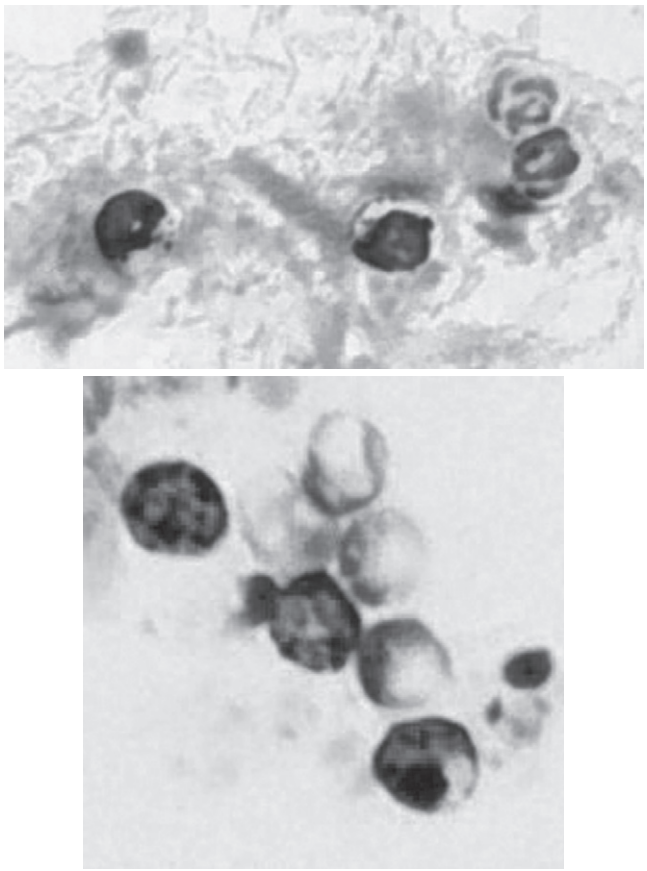

FIGURE 216-2 ■ Staining of oocysts.

Biopsy of the intestine typically is unnecessary for the diagnosis of intestinal infection, although the unique apical location within the intestinal epithelium is distinctive. The parasite can be visualized by light microscopy after staining with hematoxylin and eosin or by electron microscopy.[48]

MANAGEMENT

Replacement of fluids and electrolytes is a crucial first step in management, as with all cases of diarrhea. Oral rehydration is preferred, but severely ill patients may require parenteral fluids. Glutamine supplementation may improve fluid absorption.[25] Dietary management is crucial in cryptosporidiosis, especially if it is associated with persistent diarrhea. Supportive care should include initially a lactose-free diet because lactase activity is decreased on the apical border of epithelial cells.[166]

Cryptosporidiosis is associated with increased intestinal transit, which could interfere with absorption of fluids, electrolytes, and drugs.[19,186] Antimotility and antisecretory agents (i.e., tincture of opium, loperamide, octreotide, and acetorphan) have roles in therapy, but their use generally is limited to refractory cases in adults with AIDS.[64,188] These agents may control the diarrhea, but they do not eradicate the parasite.

In immunocompromised hosts, management of intestinal cryptosporidiosis is problematic. For patients with AIDS with chronic cryptosporidiosis, effective antiretroviral therapy can result in dramatic improvement in diarrhea.* The HIV protease inhibitors have anticryptosporidial activity in vitro and reduced infection by 90 percent in an animal model,[92,135] and most of the studies reporting responses have used protease inhibitors. By contrast, cryptosporidiosis is associated with malabsorption of nucleosides.[21] Similarly, reversal of immunosuppression may be a key component of management of severe cryptosporidiosis in transplant patients.[108,113] Patients with X-linked immunodeficiency with hyper-IgM may respond to a CD40 agonist antibody.[58]

The role of antiparasitic therapy in cryptosporidiosis is controversial. Because cryptosporidiosis usually is self-limited in immunocompetent hosts and can be variable in compromised hosts, controlled trials are crucial. No agent has proved reliably curative in patients with advanced AIDS. A meta-analysis of seven randomized controlled clinical trials found no clear evidence for efficacy of antiparasitic agents in the management of cryptosporidiosis in compromised hosts.[1]

Nitazoxanide is a nitrothiazolyl-salicylamide derivative with a broad spectrum of antiprotozoal and antihelminthic activity.[157a] Nitazoxanide is active against *Cryptosporidium* in vitro and in animal models.[67,196] A placebo-controlled study of nitazoxanide in patients with cryptosporidiosis showed significant clinical improvement in apparently immunocompetent children and adults with persistent diarrhea.[178] By day 7, diarrhea had resolved in 39/49 (80%) patients treated with nitazoxanide in contrast to 20/49 (41%) treated with placebo. Nitazoxanide also reduced the duration of shedding of oocysts. In parallel randomized studies in severely malnourished HIV-infected and HIV-negative children in Zambia with chronic cryptosporidiosis, a 3-day course of therapy not only led to clinical and parasitologic improvement, but also improved survival in HIV-negative children.[8] All children were treated with nitazoxanide suspension (100 mg twice daily for 3 days) or matching placebo. Among non–HIV-infected patients, resolution by day 7 was noted in 14/25 (56%) of patients treated with nitazoxanide in contrast to 5/22 (23%) for the placebo group. Similar findings were reported in immunocompetent patients 12 years of age and older. A good clinical response was seen in 27/28 (96%) patients receiving nitazoxanide in contrast to 11/27 (41%) receiving placebo.[179] Among the HIV-infected children, most with severe malnutrition, no significant response occurred.[8] A second study using higher doses and prolonged therapy in children with HIV and cryptosporidiosis also did not demonstrate efficacy.[9]

Nitazoxanide suspension was approved in the United States in 2002 for treatment of cryptosporidiosis and giardiasis in children. For most indications, it is dosed every 12 hours for 3 days. The recommended dose is 100 mg (5 mL) for children 12 to 47 months of age, 200 mg for children 4 to 11 years, and 500 mg for older children and adults (~15 mg/kg/day).[208] Nitazoxanide generally is well tolerated; adverse events occur at a frequency similar to that for placebo and include abdominal pain, diarrhea, vomiting, and headache.[208] Although unproved, nitazoxanide and other antiparasitic drugs should be considered as an adjunct to antiretrovirals or reversal of immunosuppression in children with severe cryptosporidiosis.[141] Combinations of nitazoxanide with other agents (e.g., paromomycin and azithromycin) have been used in some severely compromised patients.

Paromomycin is an orally administered nonabsorbable aminoglycoside. Initial in vitro studies noted poor activity against *C. parvum*. When patients with AIDS and cryptosporidiosis were treated with available antiparasitic drugs, however, some improved when treated with paromomycin.[71] Three randomized, controlled trials examined the effects of paromomycin in patients with AIDS and cryptosporidiosis.[88,98,211] Paromomycin was associated with a significant reduction in shedding of oocysts and decreased stool frequency, but not cure.[211] In another study, no significant difference was found between groups.[88]

Macrolide antibiotics, including spiramycin, azithromycin, roxithromycin, and clarithromycin, have some activity against *Cryptosporidium*.[15] In one study, children treated with spiramycin had shorter duration of symptoms and shedding of oocysts,[180] but a second trial showed no effect.[213] Case series noted improvement in cryptosporidiosis in patients with HIV and cancer treated with azithromycin,[53,89,96,150] but subsequent trials in patients with AIDS did not show changes in frequency of stools or shedding of oocysts.[15] A study in Egyptian schoolchildren suggested more rapid resolution of symptoms was achieved with azithromycin.[6] Roxithromycin treatment was associated with improvement in AIDS-associated cryptosporidiosis in two uncontrolled studies.[191,201]

PREVENTION

In hospitals and daycare centers, hand washing is the most important measure to prevent the spread of any enteric pathogen. Alcohol rubs may not be adequate. Enteric precautions (i.e., washing hands, wearing gloves, and wearing gowns if soiling is likely) are important measures to prevent nosocomial spread.

*References 28, 63, 79, 126, 138, 160.

Swimming pools are an important source of infection. Contamination of treated recreational water, such as a fecal accident in a swimming pool, should prompt aggressive measures, including closing the pool temporarily.[31,33] Recreational waters, such as lakes, may pose a danger for compromised hosts, who should avoid contact with untreated water.[141]

Control of waterborne transmission of cryptosporidiosis is a major public health concern. This issue is complicated by the ability of *Cryptosporidium* to escape the filtration system used in most public water facilities and its resistance to chlorination. The Centers for Disease Control and Prevention (CDC) recommends that during outbreak situations, compromised patients boil tap water for 1 minute or filter tap water using a filtration system to remove particles 1 μ or larger, or use bottled water prepared by distillation or reverse osmotic filtration.[32] In situations not associated with an outbreak, no special measures are recommended. However, routinely using the outbreak measures outlined earlier for severe immunosuppressed patients may be prudent.[141] The CDC website contains an excellent patient fact sheet about *Cryptosporidium* and its prevention (http://www.cdc.gov/parasites/crypto). Currently, no vaccine is available to protect against *Cryptosporidium*. Vaccines for cryptosporidiosis are in development stages, but, as of this writing, none have progressed to human trials.*

CHAPTER 217

Cyclosporiasis, Cystoisosporiasis, and Microsporidiosis

A. Clinton White, Jr. • Carlos Seas • Martin Montes

CYCLOSPORA CAYETANENSIS

Cyclospora cayetanensis is an intestinal coccidian protozoan parasite, related to *Toxoplasma*, *Cryptosporidium*, *Sarcocystis*, and *Cystoisospora*. This parasite infects the gastrointestinal tract of returning travelers, and immunocompromised patients causing acute diarrheal disease.[2,54,55,117,169] In 1979, *C. cayetanensis* was first identified by Ashford[10] in the stool of a woman and two children from Papua New Guinea. *C. cayetanensis* was identified in four patients with diarrhea after travel to Mexico and Haiti.[144] The organisms were identified in stools from travelers and expatriates in Nepal. Subsequent studies noted an association with diarrhea in patients with acquired immunodeficiency syndrome (AIDS) patients.[2,117,140,168,169]

Microbiology and Life Cycle

The oocysts of *C. cayetanenesis* found in stool are round, measuring 8 to 10 m.[109] In reports from the late 1980s and early 1990s, the taxonomy was in doubt and the organisms were referred to as *Cyanobacterium*-like body, a blue-green algae, a coccidian-like body, *Cryptosporidium*-like, or big *Cryptosporidium*.* Ortega and colleagues[109,113] demonstrated sporulation and excystation of the organisms, characterizing them as a coccidian species and suggesting the name *C. cayetanensis*.[168] Molecular studies have confirmed that the organisms are coccidian parasites closely related to the *Eimeria*.[120] Humans are the only known host of *C. cayetanensis*.

Infected patients pass unsporulated oocysts into the environment. A period of 1 to 2 weeks in a warm, moist environment is required for maturation into an infectious, sporulated oocyst.[142,146] In vivo, excystation of mature sporulated oocysts most likely occurs in the small bowel. In vitro, a combination of bile salts, sodium taurocholate, and mechanical pressure is required for excystation.[146] After excystation, the sporozoites invade the intestinal epithelical cells, where they undergo first asexual and later sexual reproduction. Sexual and asexual stages of *Cyclospora* are found in jejunal biopsy specimens from infected individuals, showing that this coccidian parasite can complete its entire life cycle in a single host.[111]

Epidemiology and Transmission

Cyclospora is found worldwide. Initial reports of cyclosporiasis involved residents of or travelers returning from resource-limited countries.[59,109,113,122,139] The organism has been acquired in numerous geographic areas, including North, Central, and South America; the Caribbean islands; Europe; Turkey; northern, central, and southern Africa; southwest, southern, and eastern Asia; and Papua New Guinea and Australia.† In one study of diarrheic stool from subjects returning from tropical areas, *C. cayetanensis* was identified in 5 percent of samples, rendering it the second most common pathogen after *Giardia*.[156] Seasonal variation has been described.[59,109,172] In Nepal, most cases occur during the rainy season, between May and October.[59] In Peru, the peak is during the fall, between April and June.[109] The prevalence in endemic regions varies with the age and immunologic status of the host. Prevalence rates in children from Peru and Nepal are reported to range from 2 to 18 percent.[59,109] In a Venezuelan review, Chacin-Bonilla and associates[26] report a prevalence that ranges from 0 to 41.6 percent. In one series from Haiti, *Cyclospora* was reported in 11 percent of adults infected with human immunodeficiency virus (HIV), but was not detected in non–HIV-infected adults or infants younger than 6 months.[117]

Hall and associates[54] published an active surveillance of *C. cayetanensis* cases in the United States. They noted 370 cases and significant association to travels and outbreaks.[54]

Direct person-to-person transmission is unlikely to occur because a period outside the host is required for maturation into a sporulated oocyst.[146] Contamination of the environment with oocysts plays a major role in the transmission of *Cyclospora*. Foodborne and waterborne transmission of *Cyclospora* have been described.[52,65,98,146] Waterborne outbreaks have been reported in Chicago and Nepal.[24,62,168] In one area of Egypt, the average prevalence of *Cyclospora* spores in stool samples was 5.6 percent in patients with diarrhea, in contrast to 2.3 percent in asymptomatic subjects, with higher prevalence in places with higher water contamination.[45] High levels of aquatic contamination also were documented in Hanoi (Vietnam), reaching 63.6 percent in certain areas, again emphasizing the important role of contaminated water in the spread of the pathogen.[97]

Foodborne outbreaks have been reported frequently.[52,55-57,65,98] Eleven foodborne outbreaks occurred in North America between 1990 and 2000, affecting 3600 people.[92] For example, widespread outbreaks of cyclosporiasis occurred in the United States and Canada in 1996 and 1997 associated with the consumption of raspberries imported from Guatemala.[55-57] Researchers postulated that the raspberries were contaminated with insecticide or fungicides that were mixed with contaminated water or that the irrigation water was contaminated with *Cyclospora* oocysts.[114,142] During 1997, clusters of cases were identified in which fresh basil and mesclun lettuce were implicated.[124] *Cyclospora* oocysts contaminating vegetables are not removed easily by routine washing.[111]

Clinical Manifestations

Cyclospora affects both immunocompetent and immunocompromised patients.* The incubation period typically is 2 to 11 days.[24] In immunocompetent host, diarrhea may last up to 7 weeks.[168] Relapsing diarrhea alternating with constipation is the rule.[142] Resolution of symptoms usually correlates with disappearance of the organism from stool.[59,116] Asymptomatic oocysts also occurs.[17,122] In one prevalence study in a Venezuelan community, *C. cayetanensis* oocysts were identified in 6.1 percent of subjects, of whom 84.6 percent were asymptomatic.[27]

In immunocompromised hosts, especially, onset of watery diarrhea may be abrupt or gradual. Malaise, myalgia, and anorexia, are common.[30,168] Low-grade fever is reported in approximately 25 percent of patients.[24,59,139,168] Vomiting may occur but is less common than diarrhea. Other associated symptoms include abdominal cramping, heartburn, and indigestion.[142] Weight loss and malabsorption occur with prolonged illness.[59,60,144,169]

The median duration of disease in various U.S. outbreaks has been 10 to 20 days (range, 1 to 60 days).[55] In HIV-infected patients, *Cyclospora* causes symptoms that are indistinguishable from symptoms of *Cryptosporidium* and *Cystoisospora* infection.[168] Biliary disease was reported in two patients with AIDS infected with *Cyclospora*. These patients had clinical and radiographic confirmation of biliary disease and did not have evidence of infection with

other pathogens. Both patients had acalculous cholecystitis that was responsive to therapy with trimethoprim-sulfamethoxazole (TMP-SMX).[144] *Cyclospora* also has been identified in respiratory secretions of immunocompromised patients.[64]

Diagnosis

Cyclospora can be visualized by light microscopy on wet mounts or after formol-ether concentration of the stool. In fresh stool, the oocysts are unsporulated. They appear as refractile spherical bodies measuring 8 to 10 μm and have a central greenish morula that contains six to nine refractile globules.[113] Safranin staining enhances the outline of the membrane, but does not stain internal structures. Galvan-Diaz and colleagues[49] compared safranin and Ziehl-Neelsen stains using as gold standard the direct visualization of the parasite. They found a sensitivity of 95 percent and specificity of 98 percent with safranin staining and a sensitivity 90 percent and specificity of 100 percent for Ziehl-Neelsen staining.[49]

The sensitivity of wet mounts is 75 percent.[117] Oocysts exhibit bright blue autofluorescence when exposed to ultraviolet light. Auramine-rhodamine staining enhances the visualization of internal structures. Staining is variable with modified Ziehl-Neelsen stain (Fig. 217-1).[109] *Cyclospora* is not visualized by Gram, Giemsa, Grocott-Gomori methenamine–silver nitrate, Lugol iodine, periodic acid–Schiff, or hematoxylin and eosin staining.[118,168]

A direct comparison of formalin-ether sedimentation, direct smear examination, and sucrose centrifugal flotation yielded the highest recovery of *Cyclospora* oocysts in stool with the last method.[76] More recently, polymerase chain reaction (PCR)[63,79,81,154,156] and flow cytometry[44] have been studied as more sensitive detection methods.

Treatment

When treatment is indicated because of the severity or persistence of symptoms, TMP-SMX is the drug of choice.[60,88,89,155] No clear alternatives are available in patients who are intolerant of TMP-SMX. Ciprofloxacin was inferior to TMP-SMX in patients with AIDS.[155] Nitazoxanide has been used in a limited number of patients.[173] Prophylaxis with TMP-SMX 3 days per week seems to prevent recurrent episodes in HIV-infected patients.[117]

CYSTOISOSPORIASIS

Cystoisospora belli (previously known as *Isospora belli*) is an intestinal coccidian parasite (Fig. 217-2). Human infection was first recorded in U.S. military personnel during World War I. The first U.S. cases were described in children with chronic diarrhea and malnutrition.[21] *C. belli* causes acute and chronic diarrhea in immunocompetent children but can cause prolonged, life-threatening diarrhea and volume depletion in patients with compromised cellular immunity, particularly among patients infected with HIV.[58,129]

Microbiology and Life Cycle

C. belli is a coccidian parasite.[84] The taxonomy was recently revised separating the genus *Isospora* with organisms that infect birds reclassified as *Atoxoplasma* and those infecting mammals as *Cystoisospora*.[15] Some species of *Cystoisospora* infect other mammals, but only *C. belli* infects humans.[84] Mature oocysts of *C. belli* are oval, measure 10 to 20 mm × 20 to 33 μm, with a translucent thin wall that contains two round sporoblasts, each with four crescent-shaped sporozoites (Fig. 217-3).[31] Humans acquire the infection by ingesting food or water contaminated with the mature sporulated oocyst. Excystation occurs in the proximal part of the small intestine, leading to the release of sporozoites that invade enterocytes of the distal duodenum and proximal jejunum and develop into trophozoites. The trophozoites reproduce asexually to form merozoites. The merozoites undergo asexual replication (schizogony or merogony) or sexual replication (gametogony) that results in the production of an immature unsporulated oocyst. This latter form is excreted in stool

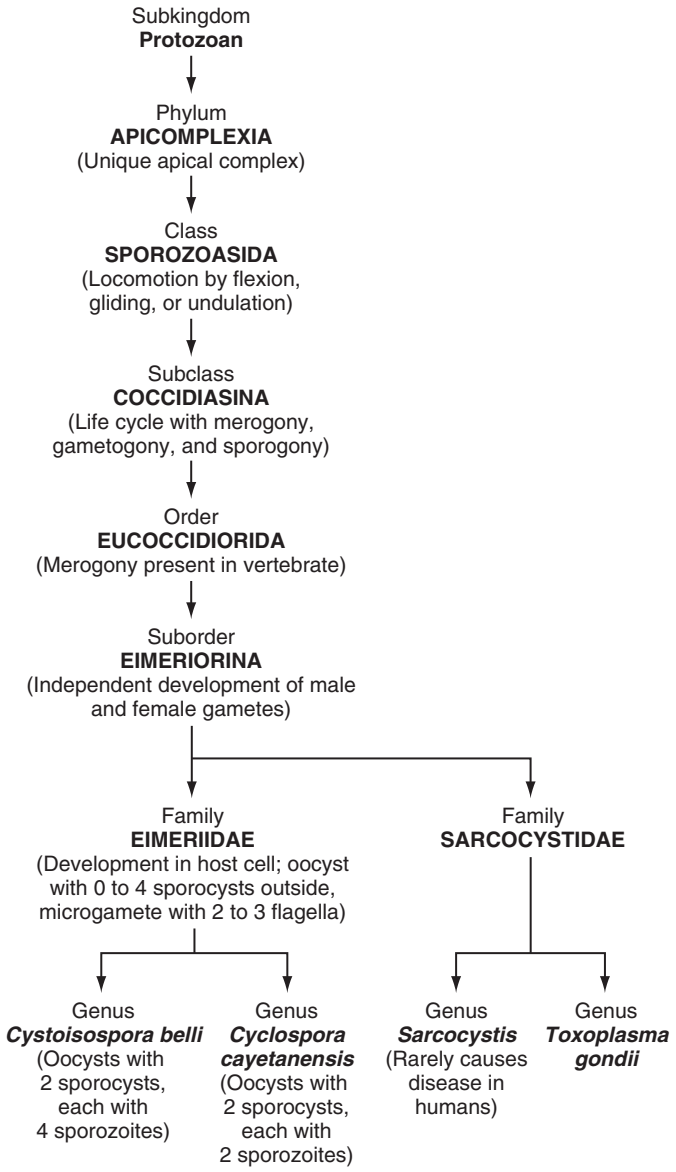

FIGURE 217-2 ■ Taxonomic classification of *Cryptosporidium, Isospora, Cyclospora,* and *Sarcocystis*.

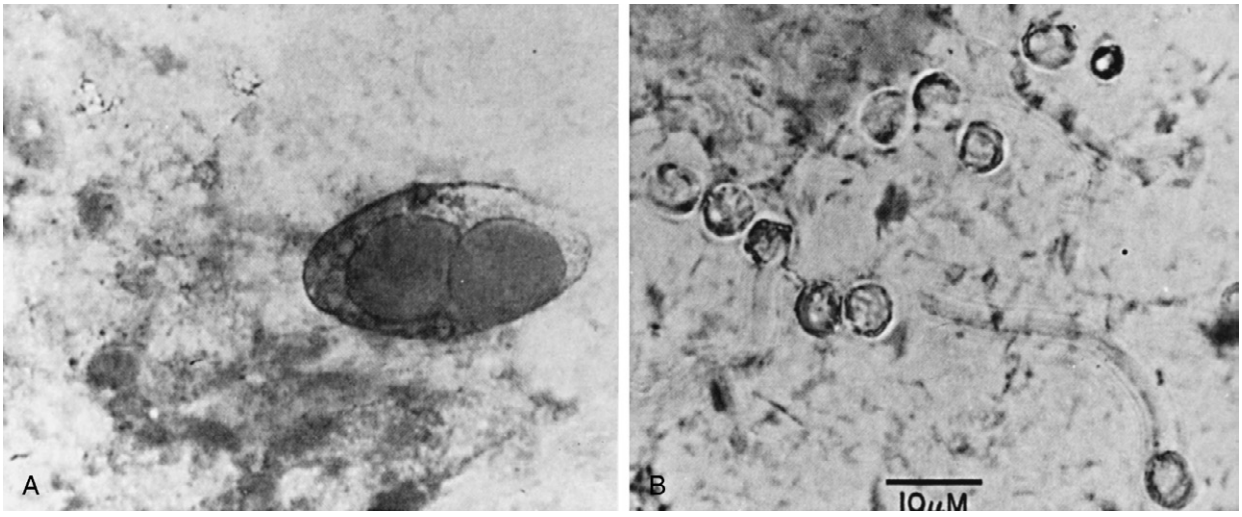

FIGURE 217-3 ■ Unconcentrated fresh stool sample from two patients with AIDS stained with modified Kinyoun stain. **A,** *Isospora belli*. **B,** *Cryptosporidium*. Note the difference in size and shape of the two coccidian parasites; *Isospora* averages 25 × 15 μm and contains two sporoblasts, whereas *Cryptosporidium* averages about 5 μm in diameter. (From DeHovitz JA, Pape JW, Boncy M, et al. Clinical manifestations and therapy of *Isospora belli* infection in patients with the acquired immunodeficiency syndrome. *N Engl J Med* 1986;**315**:87–90.)

and requires 12 to 48 hours to mature into the infectious form, a sporulated oocyst.[84]

Epidemiology and Transmission

C. belli is distributed worldwide but most cases are reported from tropical and subtropical regions. Travel to or immigration from resource-poor areas is the main risk factor for infection among cases in Europe and North America, including in patients with HIV and AIDS.[4,53,78,137,145] The incidence of *C. belli* among HIV-infected patients with chronic diarrhea in the developing world varies markedly, with very high rates of 13 to 26 percent of patients with diarrhea in Venezuela, Haiti, and India.[1,25,37,158] Infection is also common in Egypt, sub-Saharan Africa, Brazil, and other parts of Asia, but recorded rates have been lower.[141,161,167] On the other hand, *C. belli* is less common among HIV-infected patients taking cotrimoxazole prophylaxis.[23,53]

Transmission is by the fecal-oral route. However, direct person-to-person transmission is considered very uncommon, because the immature oocysts shed by humans require at least 1 to 2 days in the environment to become infectious.[37,84] The incubation period is thought to be 3 to 14 days.[84] The infectious dose is largely unknown. The oocysts of *C. belli* are resistant to commonly used disinfectants and may remain viable for months.

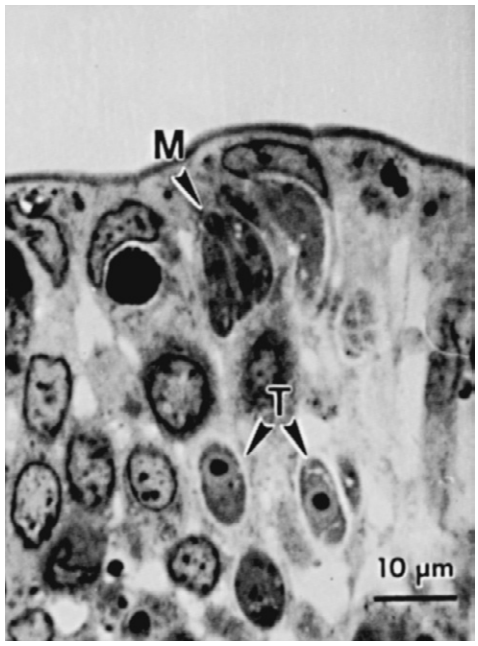

FIGURE 217-4 ■ *Isospora* infecting the jejunum of a patient with severe diarrhea. Trophozoites *(T)* divide within enterocytes by schizogony to form merozoites *(M).* (From Garcia LS, Owen RL. Current WL. Isosporiasis. In: Balows A, Hausler WJ Jr, Ohashi M, Turano A, editors. *The laboratory diagnosis of infectious diseases: principles and practice.* vol. 1. New York: Springer-Verlag, 1988, p. 899–903.)

Pathophysiology

The pathologic findings are nonspecific. Typical histopathologic findings include shortening of the villi; hypertrophy of the crypts; and infiltration of the lamina propria with plasma cells, lymphocytes, polymorphonuclear leukocytes, and eosinophils.[46,103] All stages of the life cycle have been identified within the villous epithelium (Fig. 217-4). *C. belli* also can cause biliary tract infection.[159] The pathophysiology of cystoisosporiasis has not been defined, but the organisms are strongly associated with diarrhea and malabsorption syndromes.[9,16,153]

Clinical Manifestations

The main clinical manifestation of cystoisosporiasis is nonbloody, watery diarrhea. However, the spectrum of disease ranges from asymptomatic infection to life-threatening diarrhea. Immunocompetent patients usually have a self-limited illness, although diarrhea may not resolve for several weeks.[74,99,153] Some children have chronic malabsorption.[16] Headache, malaise, vomiting, fever, and dehydration may be noted. The disease is more severe in infants and children than in adults. In contrast to other protozoan parasites, *C. belli* is strongly associated with peripheral eosinophilia, which can be marked.[25,72]

The clinical course of cystoisosporiasis in immunosuppressed children depends on their cellular immunity. HIV-infected patients with CD4 cell counts below 200 cells/mm^3 are particularly at risk for becoming infected and to present symptoms, usually for prolonged periods with intermittent bouts of reactivation.[9,13,78] Patients who have a reconstituted immune system as a result of effective antiretroviral therapy are seldom symptomatic.[14] Seasonality has been observed in some but not all studies from developing countries.[25,35] Other conditions associated with depressed cellular immunity, including lymphomas and organ transplantation, predispose to a more severe illness.[127,128] The onset of illness is insidious and is associated with nonspecific symptoms, such as low-grade fever, headache, malaise, myalgia, and anorexia. Nausea, vomiting, and diffuse abdominal pain may be present as well. The diarrhea is typically watery. Severe dehydration, hypokalemia, metabolic acidosis resulting from bicarbonate losses, and azotemia may occur.[129,165] Marked weight loss, reaching 30 percent of body weight, has been reported in a patient with a 9-month clinical course.[129] Elevated stool osmolality and steatorrhea, are also common findings.

Extraintestinal manifestations of *C. belli* are rare; gallbladder and biliary tract infections have been reported in both HIV-infected and immunocompetent patients.[18,48,159] Cholangitis defined as elevation of alkaline phosphatase and dilation of the common bile duct detected by ultrasound was found in 4/28 patients chronically infected in France.[78] The organism has been identified in tracheobronchial, mediastinal, and mesenteric lymph nodes; the spleen; and the liver.[96]

Diagnosis

C. belli infection is usually diagnosed by observing oocysts in a stool wet-mount preparation or using modified acid-fast or auramine-rhodamine stain (http://dpd.cdc.gov/

dpdx/Html/Cystoisosporiasis.htm).[110] Concentration techniques such as zinc sulfate, hypertonic sodium chloride, formalin-ether sedimentation, and Sheather sucrose solution are recommended to increase the sensitivity. Multiple stool samples may be required to make the proper diagnosis. The oocysts are oval, contain one or two sporoblasts, and are 10 times larger than *Cryptosporidium* oocysts. Like *Cyclospora*, the oocysts of *C. belli* exhibit autofluorescence with an ultraviolet epifluorescent illuminator (450- to 490-nm excitation filter). Histologic examination of the small bowel shows nonspecific findings, but asexual and sexual stages of the parasite can be observed within the enterocytes[22] (Fig. 217-5). *C. belli* can be found infecting the small and large intestine in patients with HIV and AIDS. Peripheral blood eosinophilia and Charcot-Leyden crystals in stool specimens are present in most cases.[72] PCR can increase detection of *C. belli* and multiplex PCR methods allow for detection of other coccidian parasites at the same time.[103,149,150] However, these methods are expensive and not widely available.

Treatment

Treatment includes careful attention to fluid replacement, nutritional support, antimicrobial therapy, and, in patients with HIV, antiretroviral therapy. Immunosuppressed patients tend to experience higher degrees of

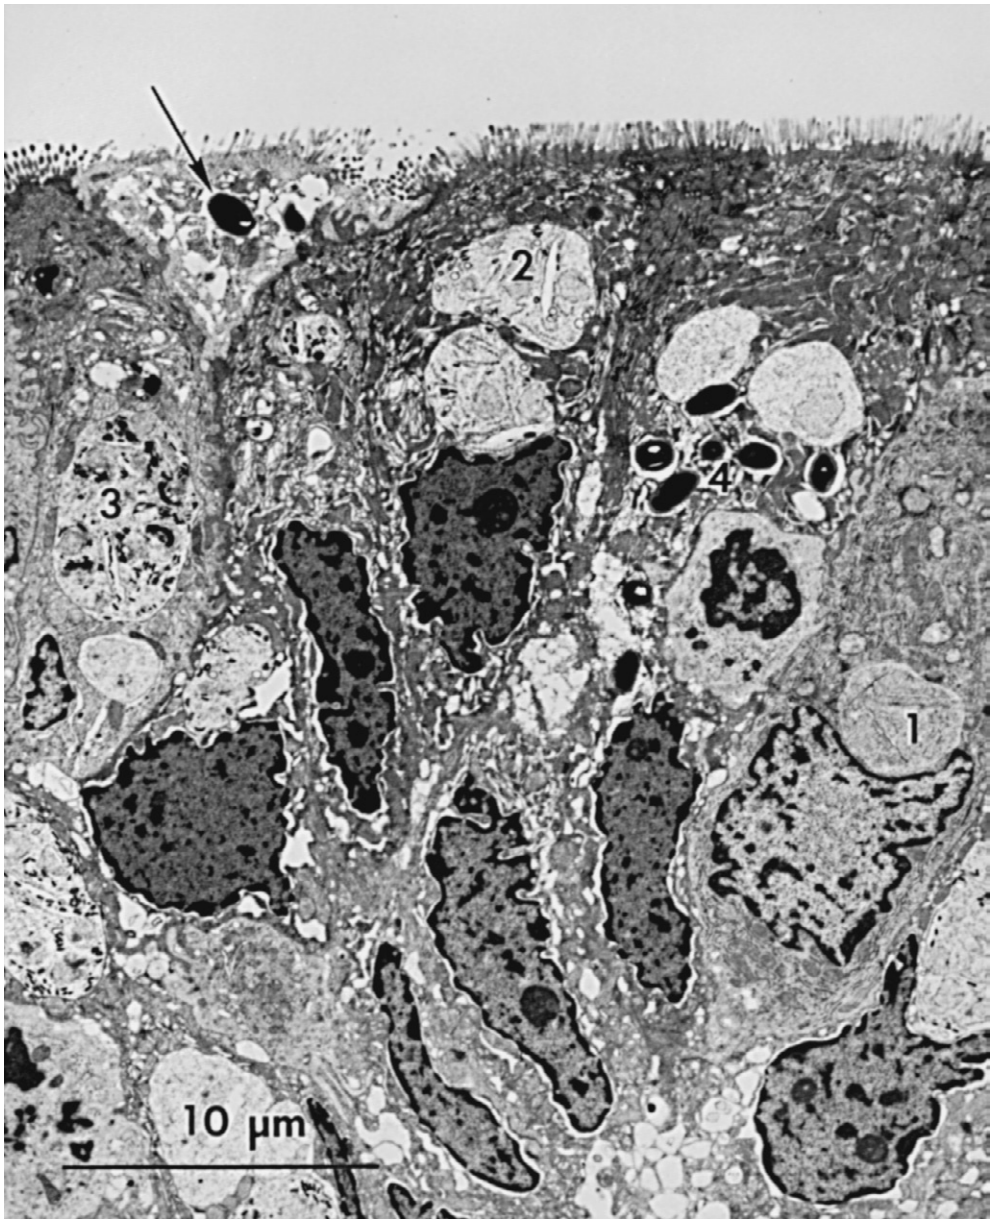

FIGURE 217-5 ■ Jejunal biopsy from a patient with AIDS and severe diarrhea. Various developmental stages of the intestinal microsporidian *Enterocytozoon* infect almost every enterocyte. Stages include proliferative plasmodia (1), early sporogonial plasmodia (2), late sporogonial plasmodia (3), and mature spores (4). A spore *(arrow)* can be seen within a necrotic enterocyte, which appears ready to slough into the lumen. (From Cali A, Owen RL. Intracellular development of *Enterocytozoon:* a unique microsporidian found in the intestine of AIDS patients. *J Protozool* 1990;**37**:145.)

dehydration than immunocompetent patients. In addition, the presence of *C. belli* and other coccidian parasites among HIV and AIDS patients has been associated with higher mortality rates.[43] Patients with severe dehydration require intravenous fluids and electrolyte support, with particular consideration to correction of hypokalemia, metabolic acidosis, and children coinfected with *C. belli* and other coccidian parasites, hypoalbuminemia, and malabsorption of vitamins and fats are commonly described. Hence, careful nutritional support is highly advised in these patients. Patients with mild-to-moderate dehydration who can tolerate the oral route should be offered oral rehydration solutions.

TMP-SMX (TMP 10 mg/kg/day and SMX 50 mg/kg/day or TMP 160-mg and SMX 800-mg tablet for adolescents) is the drug of choice. For immunocompetent hosts, one dose two times per day for 7 to 10 days is curative in most cases.[37,155] Patients with HIV or AIDS may require higher doses. The current recommendations for these patients are to start with TMP 5 mg/kg and SMX 25 mg/kg two times per day and observe the response, which usually occurs within 2 to 3 days; if no response is observed the recommendation is to increase the dose to one tablet four times per day for 7 to 10 days. Children who do not respond may have malabsorption of the drug, and, in these patients, parenteral therapy may be considered. Patients with HIV or AIDS present more frequent drug reactions to the sulfa component (SMX) than normal hosts.[71] Clinical data are very limited on treatments alternative to TMP-SMX. Ciprofloxacin may have some activity, but it is inferior to TMP-SMX.[155] Pyrimethamine with or without a long-acting sulfonamide is an alternative agent, and has worked in some cases refractory to TMP-SMX.[67,162] Nitazoxanide has in vitro activity, but clinical data are limited to case reports with both successes and failure.[19,108] Recurrences are very common among patients with HIV or AIDS; therefore, secondary prophylaxis is indicated. Current recommendation includes either TMP 5 mg/kg and SMX 25 mg/kg three times per week or pyrimethamine (25 mg) plus sulfadoxine (500 mg) once a week. Prophylaxis should be continued until the CD4 cell count is out of the AIDS range. However, failure to eradicate *C. belli* even in patients with immune reconstitution has been reported.[22]

MICROSPORIDIOSIS

Microsporidiosis comprises a diverse group of infectious diseases caused by the single-cell eukaryotic pathogens from the phylum Microsporidia, formerly termed Microspora.[42,162,166] *Microsporidia* were first identified in 1857 as pathogens of silkworms. The first human infection was described only in 1959, when the organisms were found in the spinal fluid of a Japanese child with seizures. Widespread human infection was initially recognized during the 1980s in AIDS patients. For over a century, the organisms were misclassified as protozoan parasites. However, molecular studies have clarified that the organisms were recognized as a unique phylum, closely related to the fungi. *Microsporidia* have been associated with a wide range of human infections, but most cases present with keratoconjunctivitis or diarrheal disease.

Microbiology and Lifecycle

The phylum Microsporidia includes over 170 genera with more than 1200 species.[163] Eight genera and 14 species have been identified in human infections (Table 217-1). Recent classification schemes reflecting emerging genomic sequences include them with fungi in the Opisthokonta supergroup. All are obligate intracellular pathogens. Their hosts include every animal phyla and some protozoa. Their genomes are highly compact, ranging from 2.3 to 19.5 Mb, with some of the smallest eukaryotic genomes, with few introns, high gene density, and shorter protein sequences than noted for corresponding genes in *Saccharomyces cerevisiae*.[33,75,119,123] Although the organisms were initially thought to be primitive eukaryotic

TABLE 217-1 **Microsporidia Implicated in Human Disease**

Genus	Species	Main Clinical Manifestation
Enterocytozoon	*E. bieneusi*	Chronic diarrhea
Encephalitozoon	*E. intestinalis* (syn *Septata*)	Chronic diarrhea
	E. hellem	Keratoconjunctivitis, disseminated infection
	E. curriculi	Disseminated infection, seizure
Trachipleistophora	*T. anthropophthera*	Disseminated infection
	T. hominis	Myositis
Pleistophora	*Pleistophora* spp.	Myositis
Annacaliia (syn. *Brachiola*)	*A. vesicularum*	Myositis
	A. connori	Disseminated infection
	A. algerae	Keratoconjunctivitis
Nosema	*N. ocularum*	Keratoconjunctivitis
Vittaforma	*V. corneae*	Keratoconjunctivitis
Microsporidium	*M. africanus*	Corneal ulcer
	M. ceylonensis	Corneal ulcer

organisms, recent studies have demonstrated that they are a highly evolved and divergent group of fungal organisms that are highly adapted and specialized for intracellular parasitism.

Microsporidia form characteristic unicellular spores (ranging in size from 1.0 × 3.0 μ to 1.5 × 4.0 μ) with a proteinaceous exospore, an endospore made of chitin and protein, and a plasma membrane. All spores contain a nucleus, a polaroplast, and a coiled microtubular extrusion apparatus anchored to one end of the spore. The host is infected by ingestion or inhalation of spores. Within the host, the spores undergo extrusion of the polar tube and injection of the sporoplasma into the host cell cytoplasma. Within the host cells, the pathogen undergoes cell division by either binary or multiple fission (merogony). This leads to formation of spores (sporogony), during which meront cell membranes thicken and divide to form spores. The spores are released usually by lysis of the host cell.

Epidemiology

Microsporidiosis has been identified on all continents except Antarctica.[162] Microsporidia infection appears to be common, with mainly asymptomatic or mild self-limited illnesses in normal hosts.* Prevalence is variable and can be as high as 80 percent in some populations and not detected in others. Clinical disease was initially recognized in compromised hosts, especially patients with AIDS. Microsporidia, especially *Enterocytozoon bieneusi*, are commonly detected in stools from HIV-infected children with persistent diarrhea not on effective antiretroviral therapy (up to 77% of cases, but typically about 15%).[152] Microsporidiosis is increasingly recognized in children on immunosuppression for organ transplantation.[3,51,80] However, recent studies have emphasized underdiagnosis in normal hosts, including travelers and children, especially those living in resource-limited countries.† Even minor increase in economic status can protect against disease.[107] However, a foodborne outbreak was associated with diarrhea in normal hosts in Sweden.[36,39]

Most human infections appear to be acquired by ingestion or inoculation in the eye.[39,42] Sources of ingested organisms include other people, food, and water. Person-to-person transmission was documented in an orphanage.[82] Pathogenic microsporidial spores are commonly found in surface and drinking water.[29,50] A foodborne outbreak has been described.[36] Encephalitozoon species are common in mammals and birds.[38,40,94,147] *Enterocytozoon bienuesi* has also been reported from pigs and a number of other mammalian and avian hosts.[38,39,94,134,147]

Clinical Manifestations

Microsporidiosis has been associated with a wide range of clinical manifestations. Most cases present with either diarrhea or keratoconjunctivitis. Less common manifestations include disseminated infection (including neurologic disease) and myositis. Infection of a wide range of other organs has been rarely described, including kidney, liver, central nervous system, and sinuses.

Intestinal and Biliary Tract Microsporidiosis

Human microsporidiosis was first recognized as a cause of chronic diarrhea in patients with AIDS. Most cases of intestinal microsporidiosis are caused by *E. bieneusi* and, less frequently, *Enterocytozoon intestinalis*. Other species have rarely been identified as causes of diarrhea. Cases typically present with severe immunodeficiency ($CD4^+$ cell count $<50/mm^3$).* AIDS patients typically have chronic diarrhea, often with 3 to 10 loose or watery bowel movements per day. Stools are not typically bloody or mucoid. Affected children also may have anorexia, wasting or failure to thrive, and abdominal pain. Fever is unusual. Intestinal biopsies typically reveal villus atrophy and crypt hyperplasia, and malabsorption of carbohydrates (e.g., d-xylose), zinc, and fats frequently occurs.[12,83] By contrast, only a limited degree of inflammation is noted.[133] Infection may be fatal without aggressive treatment, but may also be self-limited or asymptomatic, especially in children with higher CD4 cell counts or on combination antiretroviral therapy.[18,115] Children with malignancies or who have undergone organ transplantation also may have chronic diarrhea.[1,3,8,85] In immunocompetent children, most cases are either asymptomatic or self-limited.[106,130] However, intestinal microsporidiosis has been associated with stunting in some series.[48,102,121]

Disease may spread to the biliary tract. Biliary tract disease with acalculous cholecystitis and sclerosing cholangitis have been associated with very low CD4 counts.[48,121] Children have abdominal pain, fever, and right upper quadrant tenderness. Imaging studies may reveal dilation of the intrahepatic and common bile ducts or irregularities of the bile duct and gallbladder wall. AIDS cholangiopathy is similar to cholangiopathy associated with cytomegalovirus and cryptosporidial infection.[142]

Ocular Infection

Ocular involvement is also a common manifestation of microsporidiosis. The main manifestations are keratoconjunctivitis and stromal keratitis. Keratoconjunctivitis was initially recognized in patients with AIDS and subsequently in other compromised hosts. However, recent studies from Asia have demonstrated that it is a common and usually self-limited illness.† Most patients have a history of local trauma or exposure to contaminated water or dirt. Many cases were previously treated with topical steroids. Immunocompetent individuals usually present with a gradual onset in the week before presentation. Most complain of tearing and redness. Other frequent symptoms include the sensation of a foreign body in the eye, ocular pain, and decreased visual acuity, Most cases are unilateral. On examination, all patients have nonpurulent conjunctivitis. Most have a coarse punctate keratitis often accompanied by a superficial scar. Most cases have a

†References 34, 69, 86, 126, 135, 138, 151.

full recovery without loss of visual acuity. The clinical presentation of keratoconjunctivitis in AIDS patients and other compromised hosts is more often chronic and bilateral. However, the clinical presentation is still typically with a superficial keratoconjunctivitis.[138,148,162] Most cases in AIDS patients are thought to be caused by *Encephalitozoon* spp. However, *Anncaliia*, *Nosema*, *Vittaforma*, and *Trachipleistophora* also have been identified in immunocompetent patients with keratoconjunctivitis.

Stromal keratitis often with corneal ulceration is a more severe, but less frequent form of ocular microsporidiosis.[138] Stromal keratitis has been described only in hosts thought to be immunocompetent. Cases have been attributed to *Microsporidium* spp., *Vittaforma corneae*, and *Trachipleistophora hominis*. Patients have redness, tears, eye pain, and decreased visual acuity. Cases are often confused with herpetic keratitis. Cure usually requires surgery.

Other Clinical Presentations

Disseminated infection has been described commonly with *Encephalitozoon* spp. Many people are seropositive for *Encephalitozoon* spp., and infection has been associated with seizures, hepatitis, sinusitis, and respiratory infection.[162] Spores are frequently found in urine, reflecting common involvement of the urinary tract, even in patients with diarrhea. *Pleistophora* species, *T. hominis*, and *Anncaliia* spp. have been associated with myositis. Patients present with myalgia, weakness, and elevated muscle enzymes.

Diagnosis

The mainstay of diagnosis is the demonstration of spores or intracellular organisms in specimens from appropriate tissues. Stool microscopy remains the most commonly used technique for diagnosis in patients with diarrhea. The spores are similar in size to bacteria and do not readily stain with routine parasologic stains, so demonstration of the organisms in stool requires special stains. Chromotrope 2R (modified trichrome), Uvitex 2B, calcofluor white, and the quick hot Gram-chromotrope stains have been used to visualize spores in the stool.[40,95,162] The fluorescent stains (Uvitex 2B and calcofluor white) are more sensitive but less specific than the chromotrope stains. Fluorescent antibody kits are commercially available for identification of *Encephalitozoon* and *E. bieneusi* in water and stool. Urine specimens are frequently positive in cases with *Enterocytozoon* infection.

Organisms can be identified in tissues. Spores can be identified in conjunctival scrapings by Giemsa, Gram-chromotrope, or calcofluor white staining.[34,70] Tissue Gram stains or chromotrope 2R can be used to stain the organisms in biopsy or autopsy tissues. Occasionally, organisms are identified in intestinal biopsies when missed on stool studies. Electron microscopy can provide more precise anatomic detail but is rarely required.

Molecular assays such as PCR are increasingly being used to diagnose microsporidiosis.[47,68,126,157] The assays are more sensitive than microscopic methods. Primers are available to identify organisms to the species level.

Treatment

Microsporidiosial diarrhea is usually self-limited in immunocompetent hosts. Thus, when possible, reconstitution of the immune response plays a critical role in management. Children with AIDS should be treated with effective combination antiretroviral therapy, which often will lead to resolution of illness.[73,90]

Albendazole 400 mg twice daily is effective therapy for most microsporidial species, including a small randomized trial in intestinal infection with *E. intestinalis*.[100] It has been used in intestinal and systemic infections.[163] However, albendazole does not work for *E. bieneusi*, the most common cause of intestinal microsporidiosis.[162]

Fumagillin is active in vitro against most microsporidial species. A small randomized trial demonstrated efficacy of fumagillin 20 mg three times daily in diarrhea caused by *E. bieneusi*, mainly in AIDS patients.[101] Similar response rates were noted in transplant patients.[28] However, a substantial rate of thrombocytopenia occurs during therapy. Fumagillin is licensed in France, but not in the United States.

Keratoconjunctivitis may be self-limited or respond to minor débridement. Topical fumagillin is available for ocular use in cases of severe keratoconjunctivitis.[34] Topical quinolone antibiotics also may be effective. Systemic albendazole may improve some cases and is recommended with *Encephalitozoon* infections, which may be associated with systemic infection. Most cases with stromal keratis require keratoplasty and may require corneal transplantation.[148]

CHAPTER 218

BABESIOSIS

Peter J. Krause

The first reference to babesiosis may have been in the Bible, where a widespread murrain or plague in cattle and other domestic animals is described in Exodus, Chapter 9, Verse 3: "Behold, the hand of the Lord is upon thy cattle which is in the field, upon the horses, upon the asses, upon the camels, upon the oxen, and upon the sheep: there shall be a very grievous murrain." The word "murrain" still is used to describe red-water fever, a form of babesiosis found in cattle in parts of Ireland.[30] Babesiosis long has been recognized as an important disease in livestock, having significant economic impact in many parts of the world; the health burden of babesiosis in humans has been recognized only more recently.[30,40,70,152]

Babesiosis is a disease caused by intraerythrocytic protozoa that are transmitted by ticks from animal reservoirs. It has many clinical features similar to those of malaria. The parasite first was described in cattle in 1888 by Babes.[5] In 1893, it became the first microorganism shown to be transmitted by arthropods when Smith and Kilbourne[135] identified a tick as the vector for a species of babesiosis *(Babesia bigemina)* in Texas cattle. The first human case was described in 1957.[132] During the past 40 years, the epidemiology of the disease has changed from a few isolated cases to the establishment of endemic areas in New England, New York, and the north-central Midwest, with reports of cases from a wide geographic range in North America, Europe, Asia, Africa, Australia, and South America. Evidence indicates that the disease is more common in children and adults than is currently reported.[74,77,152]

EPIDEMIOLOGY

Worldwide, more than 100 species in the genus *Babesia* infect a wide variety of wild and domestic animals. *B. bigemina*, *Babesia bovis*, *Babesia divergens*, and *Babesia major* are found in cattle; *Babesia equi* is found in horses; *Babesia canis* is found in dogs; *Babesia felis* is found in cats; and *Babesia microti* is found in rodents.[86] Each species previously was thought to be host specific, but the host range of some species now is recognized to be quite broad.[53,85,86,139,146] Some confusion has occurred in taxonomy because the identification of different *Babesia* spp. has been based largely on morphology and the vertebrate host.[51] Most *Babesia* spp. are small (1 to 5 μm in length) and pear-shaped, round, or oval.[51,85] Six *Babesia* spp. have been found to cause disease in humans: *B. microti*, *B. divergens*, and *B. divergens*–like, *B. duncani*, *B. venatorum*, and KO1.* The complete genome of *B. microti* recently has been sequenced. It has the smallest nuclear genome of all parasites in the phylum Apicomplexa, including *Plasmodium*, *Toxoplamsma*, and *Cryptosporidia*, and has the minimal metabolic requirement for intraerythrocytic protozoan parasitism.[28] These and other data suggest that *B. microti* should be renamed, but additional phenotypic and genotypic characterization of this organism and *B. microti*–like strains and isolates are needed.

Human babesiosis is a zoonotic disease transmitted by a tick vector from an infected animal reservoir

The ticks are an adult male, an adult female, and an engorged female. **C,** White-footed mouse *(Peromyscus leucopus).* **D,** Life cycle of *B. microti.* (**B,** Courtesy Mike Frigione, Pfizer, Inc., New York. **D,** Modified from Ruebush TK II. Babesiosis. In: Strickland GT, editor. *Hunter's tropical medicine.* Philadelphia: Saunders; 1984.)

(Fig. 218-1). Humans are an uncommon and terminal host for *Babesia* spp., which depend on other species for survival. The primary reservoir for *B. microti* in eastern North America is the white-footed mouse *(Peromyscus leucopus)*, but the parasite also has been found in shrews, chipmunks, voles, and rats.[52,139,147] Two thirds of *P. leucopus* have been found to be parasitemic in endemic areas.[140] *Babesia* spp. are transmitted by hard-bodied (ixodid) ticks. The primary vector in the northeastern United States is *Ixodes scapularis* (also known as *Ixodes dammini*), which is the same tick that transmits *Borrelia burgdorferi*, the etiologic agent of Lyme disease, and the agent of human granulocytic anaplasmosis.[64,66,136-141,145,154] *I. scapularis* ticks may be infected simultaneously with *B. burgdorferi*, *B. microti*, and the agent of human granulocytic anaplasmosis.[91,106,154] Clinical and serologic evidence exists for simultaneous human infection with two or more of these pathogens.*

Each of the three active stages in the life cycle (i.e., larva, nymph, and adult) of *I. scapularis* takes a blood meal from a vertebrate host to mature to the next stage.[140] Ingested babesial organisms infect intestinal tissue of the tick and subsequently travel to the salivary glands, from which they may be introduced into a new vertebrate host.[105] *Babesia* spp. are transmitted to the subsequent tick stage (trans-stadial passage). In some species of *Babesia*, such as *B. bovis*, the organisms may invade the ovaries and pass transovarially to the larvae. The tick transmission cycle begins in late summer, when newly hatched larvae ingest the parasite with a blood meal from an infected rodent and maintain the parasite to the nymphal stage. Nymphs transmit the *Babesia* spp. to rodents in late spring and summer of the following year.[137,140] Larvae, nymphs, and adults can feed on humans, but the nymph is the primary vector.[105] All active tick stages also feed on the white-tailed deer *(Odocoileus virginianus)*, which is an important host for the tick, but is not a reservoir for *B. microti*.[107,140] An increase in the deer population during the past few decades is thought to be a major factor in the spread of *I. scapularis* and the resulting increase in human cases.[137,140] Domestic animals such as the dog may carry the adult *I. scapularis*, but do not seem to be important hosts for the tick and are not infected with *B. microti*.[124,138]

*References 8, 10, 77, 81, 88, 97, 148.

Since the 1980s, human babesiosis has been described with increasing frequency at mainland sites, and more recent studies suggest that the endemic range continues to expand.[34,63,78,152] In certain sites, in certain years of high transmission, babesiosis may constitute a significant public health burden.[74] *B. microti* has been identified in rodent populations in several regions of the United States,[2,3,41,119,139] and human cases have been reported along the East Coast from Maryland to Maine and in Minnesota and Wisconsin.* Moderately severe illness caused by *Babesia duncani* and *B. duncani*–type organisms have been reported on the Pacific Coast from northern California to Washington State.[27,68,103,109] Cases of human babesiosis caused by *B. divergens*–like organisms have been reported in Missouri, Kentucky, and Washington State.[6,54-56] The tick vectors and reservoir hosts for *B. duncani* and *B. duncani*–type and *B. divergens*–like organisms have not been definitively identified.[59,152] In Europe, *B. divergens* and *Babesia venatorum* infections are primarily transmitted by the cattle tick *Ixodes ricinus*.[13,38,39,45,60] Human cases also have been reported in Asia, Africa, Australia, and South America.† An absence of clinical cases of babesiosis in the tropics may be due to cross immunity from other endemic protozoal diseases.[65] Most human cases of babesiosis occur in the summer and in areas where the vector tick, rodents, and deer are in close proximity to humans.[137,139,142]

Babesiosis also may be acquired through blood transfusion, and more than 150 cases have been identified.‡ *B. microti* is the most common transfusion-transmitted pathogen reported in the United States.[83,151,165] Whole blood, frozen erythrocytes, and platelets have been implicated. The incubation period in these cases is usually 6 to 9 weeks but may be as long as 6 months. Transfusion-transmitted babesiosis has been reported throughout the year and in nonendemic areas. About a fifth of the cases have been fatal.[55,150,165] Although most cases of babesiosis in neonates have been acquired through blood transfusion, a few cases of transplacental transmission of babesiosis have been described.[33,36,62,152] The outcome in these cases has been good after treatment with appropriate antibiotic therapy.

PATHOGENESIS AND PATHOLOGY

Understanding of the pathogenesis and pathology of babesiosis in humans is incomplete and is based largely on information gathered from human case studies and studies of babesiosis in other animals. Rudzinska and colleagues[116,117] and Karakashian and associates[66] studied the life cycle of *B. microti* in erythrocytes using electron microscopy. After adhesion and entry into the erythrocyte occurs, the organism multiplies by asexual budding into two to four daughter cells, or merozoites. In contrast to *Plasmodium* spp. merozoites, which are released from the erythrocytes all at once (synchrony), *Babesia* spp. merozoites are released at varying intervals. New erythrocytes are infected, and the cycle is repeated.

The pathogenesis of babesia infection is closely linked to the host response to infection and modification of the erythrocyte membrane.[71] Investigation of *Babesia rodhani* suggests that activation of the alternative complement pathway allows entry of parasite into red blood cells through the C3b receptor.[60] It is unknown whether the initial merozoite release leads to destruction of the host erythrocyte, but alteration of the erythrocyte membrane and eventual lysis occur.[116,143] Erythrocyte lysis is associated with many of the clinical manifestations and complications of the disease, including fever, hemolytic anemia, jaundice, hemoglobinemia, hemoglobinuria, and renal insufficiency. The absence of synchrony decreases the possibility of massive hemolysis and may explain why patients heavily parasitized with *Babesia* spp. may be less ill than patients with *Plasmodium* spp.[143]

Babesia spp. are intraerythrocytic protozoa, and extracellular forms are seen only in heavily parasitized cases.[1,143] *Babesia* organisms do not invade fixed tissue, and evidence in animals suggests that disease results from the excessive production of proinflammatory cytokines (e.g., tumor necrosis factor), as is thought to occur with malaria.[22,25,71] The release of proinflammatory cytokines in patients with babesiosis may be initiated by contact with an important surface protein, glycosylphosphatidylinositol (GPI).[23,28] These cytokines subsequently stimulate release of downstream mediators, such as nitric oxide, that kill parasites but also may cause direct cellular damage if produced in excess.[22,24]

In addition to proinflammatory cytokine release, obstruction of blood vessels as a result of adherence of parasitized erythrocytes to vascular endothelium with accompanying ischemia and necrosis may result in cerebral abnormalities, hepatomegaly and hepatic dysfunction, and splenomegaly.[30,113,121] Although such cytoadherence appears to occur in cattle infected with *B. bovis*, it has yet to be demonstrated in human babesial infection.[25,71] A report of fatal human babesiosis with cerebral involvement was not associated with erythrocyte adherence and vascular occlusion.[25] Clinical manifestations such as hypotension, vascular congestion, and anoxia also may result from the activation of fibronectin, kallikreins, and complement.[32,162,163]

Innate and adaptive immune mechanisms limit the severity of babesial infections. The spleen plays a critical role in protection against *Babesia* spp. by (1) removing parasites from infected erythrocytes through a process known as "pitting," (2) ingesting parasites by resident reticuloendothelial cells and mononuclear phagocytes, and (3) producing antibabesial antibody.* It long has been known that splenectomized animals have more severe babesiosis than animals with intact spleens. Animals that have recovered from babesiosis and have had negative blood smears have developed parasitemia again after undergoing splenectomy.[87,125] Most fatal cases of babesiosis in humans have occurred in splenectomized individuals, although asplenia does not always result in death or even severe illness.[16,115] Other host defense mechanisms

*References 8, 17, 29, 32, 115, 152, 163.

that may help limit babesial infection include macrophages and macrophage products, such as tumor necrosis factor,[22,32,152,163] B lymphocytes,[94] T lymphocytes,[17,94,118,159] polymorphonuclear leukocytes,[131] antibody,[17] and complement.[8,163]

Age is an important factor in host defense against babesial disease in animals and humans. Most clinically apparent cases are reported in adults, but serologic surveys indicate that children are equally susceptible to infection and presumably are exposed to ticks to the same extent.[77,119,124] Almost all of the pediatric cases reported have been in neonates.[36,92,158] More recent data from a murine model of babesiosis have suggested that resistance to *B. microti* infection conferred by the adaptive immune system is genetically determined and associated with age.[153] Immunity is incomplete because parasitemia may exist for months to years in animals and up to 27 months in humans after recovery from the initial illness.[77] Reinfection may occur, although it is uncommon.

CLINICAL MANIFESTATIONS

Clinical manifestations of babesiosis range from subclinical illness to fulminating disease resulting in death. Overt signs and symptoms begin after an incubation period of 1 to 6 weeks from the beginning of tick feeding or 6 weeks to 6 months after transfusion.[55,124] The unengorged *I. scapularis* nymph is about 2 mm in length, and the patient often has no recollection of having a tick bite. In most cases, the patient has a gradual onset of malaise, anorexia, and fatigue followed by intermittent fever as high as 40° C (104° F) and one or more of the following: chills, sweats, myalgia, arthralgia, nausea, and vomiting.* Less commonly noted are emotional lability and depression, hyperesthesia, headache, sore throat, abdominal pain, conjunctival injection, photophobia, weight loss, and nonproductive cough.[69,121,142,143] In contrast to other tick-borne illnesses, such as Lyme disease, Rocky Mountain spotted fever, or tularemia, rash seldom is noted.[31] Ecchymoses and petechiae have been described.[67,143]

The findings on physical examination generally are minimal, often consisting only of fever.[1,56,81,123,142] Mild splenomegaly, hepatomegaly, or both are noted occasionally.[121,158] Slight pharyngeal erythema, jaundice, and retinopathy with splinter hemorrhages and retinal infarcts also have been reported.[69,92,100] Several abnormal laboratory findings in patients with babesiosis reflect the invasion and subsequent lysis of erythrocytes by the parasite.[69,92,119,121] Mild to moderately severe hemolytic anemia occurs, with an elevated reticulocyte count. Elevated liver enzyme levels may be detected in serum.[119] The leukocyte count is normal to slightly decreased, with a "left shift." Thrombocytopenia is common.[121] The erythrocyte sedimentation rate is elevated. Proteinuria and an elevated blood urea nitrogen and creatinine also may be noted.[67,69,89,121] The illness usually lasts a few weeks to several months, with prolonged recovery taking up to 18 months.[1,7,76,121,123,142] Parasitemia may continue even after the patient feels well. Persistent parasitemia and relapse of illness, as noted with malaria, has been described 27 months after the initial episode.[76] Highly immunocompromised patients may experience a prolonged relapsing course of illness despite standard antibiotic therapy.[72]

Some patients, especially patients who are immunocompromised or patients with *B. divergens* or *B. duncani* infection, have a more severe form of the disease consisting of fulminant illness lasting approximately 1 week and ending in death or a prolonged convalescence.* Signs and symptoms include high fever, hemolytic anemia, hemoglobinemia and hemoglobinuria, jaundice, ecchymoses, petechiae, congestive heart failure, pulmonary edema, renal failure, acute respiratory distress syndrome, and coma.† Patients coinfected with babesiosis and Lyme disease experience more severe acute illness than patients with Lyme disease alone but not babesiosis alone.[46,81,88,148] Coinfected patients usually experience moderate to severe acute illness often followed by persistent fatigue. Of patients with antibody to *B. burgdorferi*, 10 to 66 percent also have been found to have antibody to *B. microti*.[10,77,81]

Inapparent infection occurs in approximately a quarter of adults and half of children.[74] Serosurveys provide evidence of asymptomatic infection because of the disparity between seroprevalence rates and the number of indigenous reported cases of babesiosis. In a survey on Nantucket Island in Massachusetts, 2 percent of 577 random blood samples and 7.5 percent of 133 blood samples from patients with a history of tick bite or fever had *B. microti* indirect immunofluorescent antibody (IFA) titers of 1:64 or greater.[123] A survey of adults living on Shelter Island, New York showed that 6/136 (4.4%) and 7/102 (6.9%) had *B. microti* IFA titers of 1:64 or greater.[35] In a survey of Massachusetts blood donors, 29/779 (37%) from Cape Cod had *B. microti* IFA titers of 1:16 in contrast to 7/148 (4.7%) from metropolitan Boston.[108] In a serosurvey in Connecticut, 72/735 (9.5%) residents who were seropositive for *B. burgdorferi* had positive *B. microti* IFA titers of 1:64 in contrast to 8/299 (2.7%) seronegative for *B. burgdorferi*.[78] Serosurveys in Mexico, Nigeria, and Taiwan also showed high *B. microti* seroprevalence rates in contrast to the number of indigenous reported cases of babesiosis.[57,82,101]

DIAGNOSIS

Specific diagnosis of babesiosis is made by microscopic identification of the organism by Giemsa or Wright stains of thick or thin blood smears and by detection of babesial antibodies by one of several serologic tests. *Babesia* spp. are round, oval, or pear-shaped and have a blue cytoplasm with a red chromatin. The ring form is most common and is similar to the rings of *Plasmodium falciparum*.[51] *Babesia* spp. can be distinguished from *Plasmodium* spp. by (1) the absence of hemozoin pigment, which is present in older trophozoites of *Plasmodium* spp.;

*Restaurant 39, 49, 59, 67, 68, 88, 128, 143.
†Restaurant 42, 43, 49, 67, 70, 142, 143, 156.

(2) the absence of identifiable gametocytes; (3) the absence of synchronous stages within the erythrocytes; and (4) the presence of the infrequently noted tetrad or Maltese cross forms, in which four compact masses, each containing nuclear material, are joined by strands of cytoplasm.[51]

Multiple thick and thin blood smears should be examined because only a few erythrocytes are infected in the early stage of the illness, when most people seek medical attention.[51] Rapid automated differential blood analyzers may fail to distinguish erythrocytic inclusions.[14] In thick smears, the *Babesia* organism appears as a tiny red-to-purple nucleus with a thin tail of light blue cytoplasm. Maximum erythrocyte infection is approximately 10 percent in normal hosts, but up to 85 percent in asplenic individuals.[142] Usually less than 1 percent of erythrocytes are parasitized early in the course of the illness, and the laboratory investigation of possible babesiosis should include more than an examination of blood smears.

Several serologic tests have been developed to detect babesial antibodies, but the IFA assay is the most reliable.[21,75,79,121] During the acute phase of the illness, titers usually exceed 1:1024, but decline to 1:64 or less within 8 to 12 months. A babesial IFA titer of 1:1024 or greater usually signifies active or recent infection.[21,122] Although cross reactions occur to different *Babesia* spp. and *Plasmodium* spp. with the IFA test, these titers almost always are low (≤1:16).[21,20] The problem of cross reactivity with *Plasmodium* spp. is minimized in areas that have no indigenous malaria. A reliable immunoblot assay for detection of *B. microti* antibody has been developed.[127] Enzyme-linked immunosorbent assays for detection of *B. divergens* and *B. major* have been found to be superior to complement fixation and IFA procedures.[11,112,146,149]

In cases in which the presence of *Babesia* spp. is suspected but not shown by blood smears or antibody studies, babesial DNA can be amplified and detected using the polymerase chain reaction (PCR).[80,104,144] Blood from the patient also can be injected by the intravenous or intraperitoneal route into small laboratory animals such as hamsters or gerbils. If present in the patient, *B. microti* usually appears in the blood of the inoculated animal within 2 to 4 weeks.[9] This diagnostic technique is less sensitive and more time-consuming and costly than the PCR.[80]

PREVENTION AND TREATMENT

The combination of either atovaquone plus azithromycin or clindamycin plus quinine for 7 to 10 days is the recommended therapy for patients with babesiosis. Clindamycin and quinine should be given to patients with severe babesiosis. In such patients, clindamycin should be administered intravenously rather than orally, and exchange transfusion should be considered. The dosage recommendations are as follows[18,36,42,110,160]:

- Atovaquone: Children, 20 mg/kg every 12 hours (maximum 750 mg/dose); adults, 750 mg orally every 12 hours
- Azithromycin: Children, 10 mg/kg once per day on day 1 (maximum 500 mg/dose) and 5 mg/kg once per day (maximum 250 mg/dose) and orally thereafter; adults, 500 to 1000 mg on day 1 and 250 mg orally once per day thereafter; immunocompromised adults, 600 to 1000 mg/day
- Clindamycin: Children, 7 to 10 mg/kg given intravenously or orally every 6 to 8 hours (maximum 600 mg/dose); adults, 300 to 600 mg every 6 hours intravenously or 600 mg every 8 hours orally
- Quinine: Children, 8 mg/kg given orally every 8 hours (maximum 650 mg/dose); adults, 650 mg every 6 to 8 hours orally

The clindamycin and quinine combination first was used for an 8-week-old infant girl who contracted babesiosis from a blood transfusion.[158] Initially, she was thought to have malaria. Clindamycin and quinine were given after failure with chloroquine. Her favorable outcome suggested the prospective use of this combination in adults. Numerous children and adults subsequently have been treated with clindamycin and quinine, with prompt clearing of parasitemia and resolution of clinical signs and symptoms.[18,19,81,92,142]

The successful use of atovaquone and azithromycin for the treatment of malaria and for babesiosis in hamsters prompted a clinical trial to determine whether the combination would be effective in human babesiosis.[58,73,157] In the first prospective trial of antibabesial therapy in humans, atovaquone and azithromycin were compared with clindamycin and quinine in adults.[73] Adverse effects were reported in 15 percent of subjects who received atovaquone and azithromycin in contrast to 72 percent of subjects who received clindamycin and quinine. In approximately one third of subjects taking clindamycin and quinine, the apparent drug reactions were severe enough that the drugs were discontinued or the dosages decreased in contrast to only 2 percent of subjects taking atovaquone and azithromycin. The drug combinations were equally effective in clearing symptoms and parasitemia. Although rare cases of resistance to atovaquone and azithromycin have been reported, subsequent use of this combination in children and adults has shown that this combination is effective and should be used in those who have mild to moderate disease.[36,110,160,161]

Other antimicrobial agents that have been used to treat babesiosis generally are ineffective. Although chloroquine may give some symptomatic relief of fever and myalgia by its anti-inflammatory action, it often fails to clear parasitemia in guinea pigs and humans and is not recommended.[18,96] Other antimalarial drugs, such as quinacrine, primaquine, pyrimethamine, pyrimethamine and sulfadiazine, sulfadiazine, and tetracycline, have no effect on parasitemia in animals. Pentamidine isothionate has been found to decrease fever and parasitemia, but the organisms are not eradicated and the drug has proved to be ineffective in animals and humans.[37] Diminazene aceturate was effective in clearing parasitemia and clinical symptoms in one patient, but he developed Guillain-Barré syndrome during recovery, possibly as a result of receiving the drug.[126] Pentamidine and trimethoprim-sulfamethoxazole were used successfully to treat a case of *B. divergens* infection in France.[111]

Additional therapeutic measures may be necessary for people with severe babesiosis, especially those who are

immunocompromised. Partial or complete red blood cell exchange transfusion is an important adjunct therapy that can decrease the degree of parasitemia rapidly and remove toxic by-products of babesial infections.[16,61,143,152] Exchange transfusion is indicated for patients with severe babesiosis, as indicated by high-grade parasitemia (≥10%); significant hemolysis; or renal, hepatic, or pulmonary compromise.[160] No data are available to determine whether partial exchange transfusion is preferable to whole-blood exchange transfusion. For highly immunocompromised patients who experience therapeutic failure with an initial course of standard antibiotic therapy, resolution of infection may require at least 6 weeks of antimicrobial therapy, including 2 weeks after *Babesia* organisms are no longer detected on blood smears.[72]

Babesiosis can be prevented by avoiding areas in May through September where ticks, deer, and mice are known to thrive. It is especially important for asplenic individuals or other immunocompromised patients who are at increased risk for severe babesiosis, and who live or travel in endemic areas, to avoid tall grass and brush where ticks may abound. Use of clothing that covers the lower part of the body and that is sprayed or impregnated with diethyltoluamide, dimethyl phthalate, or permethrin (Permanone) is recommended for individuals who travel into the foliage of endemic areas.[30,133] A search for ticks on people and pets should be carried out and the ticks removed as soon as possible.[30] Tick removal is accomplished best with tweezers by grasping the mouth parts without squeezing the body of the tick.[31,99] Landscape-management approaches such as keeping grass mowed, clearing leaf litter, and spraying property where there is high tick density may help reduce the risk for infection.[50,90] Attempts to reduce the tick, mouse, or deer populations in endemic areas are less effective.[91,133,137] It is recommended that prospective blood donors who reside in endemic areas and who have a history of fever within the preceding 1 to 2 months be excluded from giving blood to prevent transfusion-related cases.[120] Blood donors who have had a history of babesiosis are permanently deferred from donating.[93,165] Effective *B. bovis* and *B. bigemina* vaccines have been developed for use in cattle, but no *B. microti* vaccine has been developed.[98,164]

Babesiosis is a worldwide tick-borne zoonosis that is endemic in the northeastern and northern Midwestern United States. The incidence is increasing and is greater than currently recognized. Babesiosis presents as a viral-like illness with generalized nonspecific symptoms, and diagnosis may be delayed. The diagnosis is confirmed by visualizing the organism on blood smears or indirectly by detection of *B. microti* antibody or detection of *B. microti* DNA with PCR. The disease may be severe or fatal, primarily in immunocompromised hosts, but complete recovery with antibabesial chemotherapy is the rule.

CHAPTER 219

Malaria

Rosemary M. Olivero • Elizabeth D. Barnett

Malaria is a disease of global importance. An estimated 216 million episodes of malaria resulting in 655,000 deaths occurred in 2010.[167] Worldwide, most deaths from malaria occur in children.[167] Regular transmission of malaria occurs in parts of Africa, Asia, the Middle East, Central and South America, Hispaniola, and Oceania. The infection has been imported by travel to nearly every part of the world. Because of the ubiquity of the infection and the increasing volume of international travel, being able to recognize the signs and symptoms of malaria and knowing about methods of prevention and treatment are important for health care professionals wherever they practice.[42,51]

Malaria usually is transmitted by bites of infected female anopheline mosquitoes. Disease typically results from infection with one or more of the four species of *Plasmodium* (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, or *Plasmodium malariae*) that commonly infect humans. A fifth species, *Plasmodium knowlesi*, which is a malaria parasite of monkeys, has also been identified to cause human malaria.[27] These protozoa have complex life cycles involving arthropod and vertebrate hosts. If untreated, *falciparum* malaria can progress to coma, renal failure, pulmonary edema, and death. Asymptomatic carriage may last decades in the case of infection with *P. malariae*. Relapses are common after infection with *P. vivax* and *P. ovale*. Resistance of the parasites to antimalarial agents and incomplete success in developing and maintaining programs to eradicate the mosquito vectors have contributed to making malaria a persistent worldwide challenge.

HISTORY

Malaria has been known since antiquity and probably affected prehistoric humans. Fossilized mosquitoes have been found in geologic strata 30 million years old. Descriptions of the signs and symptoms of malaria have been found in early Hindu and Chinese writing, and Hippocrates described seasonal and geographic aspects of the disease.[150] Numerous references to malaria occur in literature, ranging from Shakespeare's *The Tempest* to Laura Ingalls Wilder's *Little House on the Prairie*. The name is derived from the Italian *mal aria* ("bad air") based on recognition of the connection between malaria and swamps. One of the first methods of malaria control, draining swamps, was based on this association.

The first malaria treatment known to Europeans was bark of the cinchona tree, which was identified in the early 17th century almost 200 years before the active ingredient (quinine) was isolated. Not until the late 1800s was the vector-borne nature of malaria understood and described; for their roles in this discovery, Laveran, a French military surgeon working in Algeria, and Ross, a British military physician working in India, were awarded Nobel prizes. Further work by many investigators rounded out the current understanding of the life cycle of the malaria parasites and the complex interrelationship with vector mosquitoes.

During the 20th century, parallel efforts directed toward vector control and discovery and development of drugs to treat malaria were undertaken. The development of larvicides and insecticides permitted control of the mosquito vector. The spectacular success of house spraying with dichlorodiphenyltrichloroethane (DDT) was instrumental in eradicating malaria from most of North America and Europe and in decreasing its prevalence significantly in the Mediterranean area, the Middle East, the Far East, and parts of southern Africa.[130] The development of antimalarial drugs, stimulated largely by the need to protect soldiers during World Wars I and II during shortages of the standard antimalarial agent quinine, allowed for successful treatment of malaria cases.

The World Health Organization (WHO) launched a global campaign for eradication of malaria in 1957. Early successes, attributable to the efficacy of DDT and development of new antimalarial agents, subsequently were hindered by resistance of mosquito vectors to DDT and resistance of the parasites to antimalarial drugs. In 1969, the WHO philosophy on malaria was altered to emphasize the development of health services and research. The goals of malaria control since then have been refined and broadened to include implementation of selective and sustainable preventive measures, early diagnosis and prompt treatment, early detection or prevention of epidemics, and strengthening of local infrastructures to allow better understanding of the determinants of local transmission and malaria control.[130,150]

During 2000 through 2010, reductions of more than 50 percent in malaria cases have occurred in almost half (43/99) of the countries with ongoing transmission; eight additional countries showed downward trends. These successes are likely due to renewed global commitment to financing of malaria programs, allowing increased access to insecticide-treated mosquito nets (from 3% in 2000 to 50% in 2011), and indoor residual spraying (from 5% in 2005 to 11% in 2010), as well as increased availability of rapid diagnostic tests and artemisinin-based combination therapies.[167] Reductions in malaria control

have proven most challenging in countries with the most intense transmission, such as Comoros, Malawi, Uganda, and United Republic of Tanzania.[131,167] Ongoing challenges to global malaria elimination include maintaining local control measures; resistance to antimalarial drugs, especially to artemisinin derivatives; changes in climate; and population movement as a result of urbanization, mass displacement of populations, and international travel.[12,80,88,93,167]

Mortality from malaria, particularly in adults, was recently found to be larger than previously estimated, with increases in malaria deaths from 995,000 in 1980 to a peak of 1,817,000 in 2004. Corresponding to the decreases in malaria cases attributed to financing of global malaria programs, mortality rates decreased to 1,238,000 in 2010. The majority of malaria deaths are reported from Africa.[104]

Despite reductions in many areas of the world, in the United States in 2010 there were 1,691 reported cases of malaria, an increase of 14 percent compared with the number reported in 2009; this represents the highest number of cases reported in the United States since 1980. This trend is thought to reflect the steady growth of international travel with inadequate use of appropriate prevention measures by travelers but may also represent increased reporting.[90]

THE ORGANISM

The life cycle of malaria parasites is complex and requires a suitable population of anopheline mosquitoes and infected humans for completion (Fig. 219-1). To begin the cycle, the female anopheline mosquito injects sporozoites along with saliva in preparation for taking a blood meal from a vertebrate host. Sporozoites, the infective stage of *Plasmodium*, remain in the circulation for less than 1 hour and then migrate to the liver, where they invade hepatocytes and multiply asexually. Proliferation within hepatocytes takes approximately 1 week for

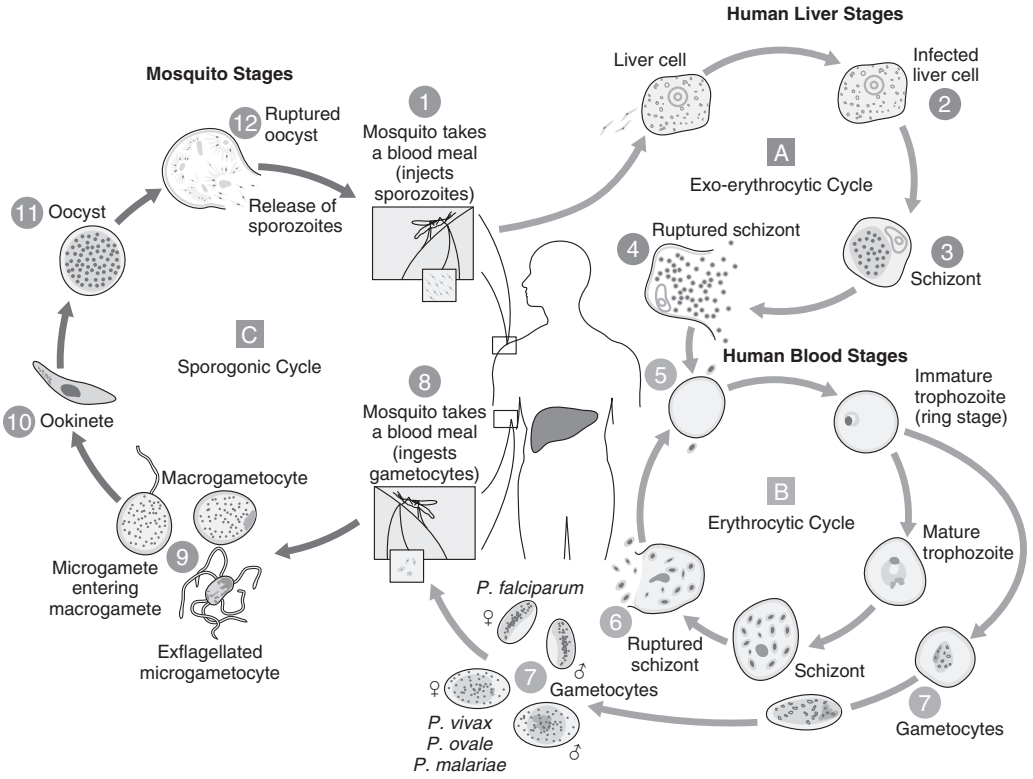

FIGURE 219-1 ■ Life cycle of the human malaria parasites. The malaria parasite life cycle involves two hosts. During a blood meal, a malaria-infected female *Anopheles* mosquito inoculates sporozoites into the human host (1). Sporozoites infect liver cells (2) and mature into schizonts (3), which rupture and release merozoites (4). (Of note, in *P. vivax* and *P. ovale* a dormant stage [hypnozoites] can persist in the liver and cause relapses by invading the bloodstream weeks, or even years, later.) After this initial replication in the liver (exoerythrocytic schizogony [**A**]), the parasites undergo asexual multiplication in the erythrocytes (erythrocytic schizogony [**B**]). Merozoites infect red blood cells (5). The ring stage trophozoites mature into schizonts, which rupture, releasing merozoites (6). Some parasites differentiate into sexual erythrocytic stages (gametocytes) (7). Blood stage parasites are responsible for the clinical manifestations of the disease. The gametocytes, male (microgametocytes) and female (macrogametocytes), are ingested by an *Anopheles* mosquito during a blood meal (8). The parasites' multiplication in the mosquito is known as the sporogonic cycle (**C**). While in the mosquito's stomach, the microgametes penetrate the macrogametes, generating zygotes (9). The zygotes, in turn, become motile and elongated (ookinetes) (10) and invade the midgut wall of the mosquito, where they develop into oocysts (11). The oocysts grow, rupture, and release sporozoites (12), which make their way to the mosquito's salivary glands. Inoculation of the sporozoites (1) into a new human host perpetuates the malaria life cycle. (From Centers for Disease Control and Prevention. *Malaria: biology,* <http://www.cdc.gov/malaria/about/biology/index.html> [accessed 11.06.13].)

P. falciparum and *P. vivax* and approximately 2 weeks for *P. malariae*. At the end of this period, mature tissue schizonts rupture and release thousands of merozoites, which then invade red blood cells (RBCs). *P. vivax* and *P. ovale* have a second type of exoerythrocytic form, the hypnozoite, which can remain dormant for weeks to years. Dormant hypnozoites may develop weeks, months, or years later into merozoites, which then can enter RBCs and cause relapse of malaria. The factors that influence which exoerythrocytic form develops are not understood.

Merozoites released from tissue schizonts invade RBCs, where the erythrocytic phase of the life cycle occurs. Two pathways exist in the erythrocytic, or blood, phase: asexual and sexual. In the asexual phase, development of the parasite begins with the youngest stage, the trophozoite or ring form. The parasite undergoes nuclear division to form schizonts and then merozoites in the asexual multiplication process, called *erythrocytic schizogony/merogony*. Lysis of RBCs releases the merozoites, which invade other RBCs, perpetuating the asexual erythrocytic cycle. The cycle continues until interrupted by treatment or by the host's immune response.

In the sexual phase, subpopulations of merozoites in the erythrocytic phase differentiate into gametocytes, or sexual forms, which then are available for ingestion by mosquitoes to complete the life cycle within the mosquito. Female macrogametocytes and male microgametocytes appear in the circulation within 3 to 15 days of the onset of symptoms. Gametocytes of *P. vivax* may appear in 4 days, whereas gametocytes of *P. falciparum* may require 10 days for development.

In the stomach (midgut) of the mosquito, male gametocyte nuclei divide into four to eight nuclei and form motile gametocytes that fertilize the female gametocytes. The zygotes become motile ookinetes that migrate through the wall of the midgut, attach to its outer surface, and form oocysts. The oocysts rupture 9 to 14 days later and release sporozoites that invade the mosquito salivary glands, where they are ready for inoculation into the next vertebrate host.

EPIDEMIOLOGY

Transmission of malaria occurs in large parts of Africa, the Indian subcontinent, Southeast Asia, the Middle East, Oceania, and Central and South America (Fig. 219-2). Although indigenous transmission of malaria has been eradicated almost completely from the United States, Canada, northern Europe, most of the Caribbean, parts of South America, Israel, Turkmenistan, Morocco, the United Arab Emirates, Armenia, Lebanon, Reunion, Singapore, Hong Kong, Japan, Korea, Taiwan, Brunei, and Australia, many cases of imported malaria occur in these countries each year.[167]

P. falciparum is the major malaria species in sub-Saharan Africa and the island of Hispaniola, with *P. malariae* assuming a more minor role. *P. vivax* occurs alongside *P. falciparum* in the Indian subcontinent, Central and South America, Mexico, Southeast Asia, and Oceania. *P. ovale* occurs mainly in Africa. *P. vivax* occurs rarely in sub-Saharan Africa because most Africans lack the Duffy blood group antigen necessary for parasite invasion.[73] *P. knowlesi* has been isolated only in Southeast Asia.[167]

TRANSMISSION

Epidemiologic Terminology

Patterns of transmission of malaria include stable endemic malaria (natural transmission occurring over many years, with a predictable incidence of illness and prevalence of infection) and unstable malaria (transmission rates vary from year to year, and immunity is low, with a greater likelihood of epidemics occurring). The degree of endemic malaria is based on the parasite rate in children 2 to 9 years old. Types of endemic malaria include hypoendemic (parasite rate of 0% to 10%), mesoendemic (parasite rate of 11 to 50%), hyperendemic (parasite rate consistently >50%, with a high proportion of adults having enlarged spleens), and holoendemic (parasite rate consistently >75%, with a low proportion of adults having enlarged spleens).[150]

Autochthonous malaria is acquired locally and may be indigenous or introduced. Introduced malaria may occur when migrant populations with asymptomatic infection provide blood meals for feeding anopheline mosquitoes under conditions that allow for the life cycle to be completed in the mosquito and enable the mosquito to infect others. Imported malaria cases may occur in nonendemic areas but result from infection in an endemic area. Induced malaria is acquired by exposure to infected blood, such as from blood transfusion, needlestick injury, laboratory accident, or, historically, medical treatments. Cryptic malaria cases are cases for which no explanation can be found and no epidemiologic link to other cases can be identified.

Mosquito-borne Transmission

The most typical means of transmission of malaria is through the bite of an infected female anopheline mosquito. Although more than 450 species of anopheline mosquito exist, only approximately 60 have been shown to be effective vectors of malaria.[24] A population of infected humans is necessary to sustain transmission because of the short life span of mosquitoes (5 to 20 days) and the long incubation period required in the mosquito (8 to ≥10 days).

Bloodborne Transmission

Transmission of malaria via blood transfusion is well documented.[103,116] Transmission also may occur through organ donation or needlestick injury.[53,163] Relapses of malaria cannot occur with bloodborne transmission, even if the infecting species is *P. vivax* or *P. ovale*, because the infection is produced by the transmission of infected RBCs rather than forms that invade the liver.

(From Centers for Disease Control and Prevention. *Infectious diseases related to travel,* <http://wwwnc.cdc.gov/travel/yellowbook/2012/chapter-3-infectious-diseases-related-to-travel/malaria> [accessed 10.05.12].)

Congenital Malaria

Infants can acquire malaria from their mothers during pregnancy. Transplacental transmission of parasites has been proposed as the most likely route of transmission, although breakdown of placental barriers allowing transmission of maternal blood cells to the infant during labor or delivery also has been suggested as a mechanism of transmission.[61,89,99] *P. vivax* most often is associated with this phenomenon, but it may occur with all species. Congenital malaria is less likely to occur in infants of semi-immune mothers because of passage of maternal antibody at the time of birth. As with transfusion-associated malaria, relapses do not occur.

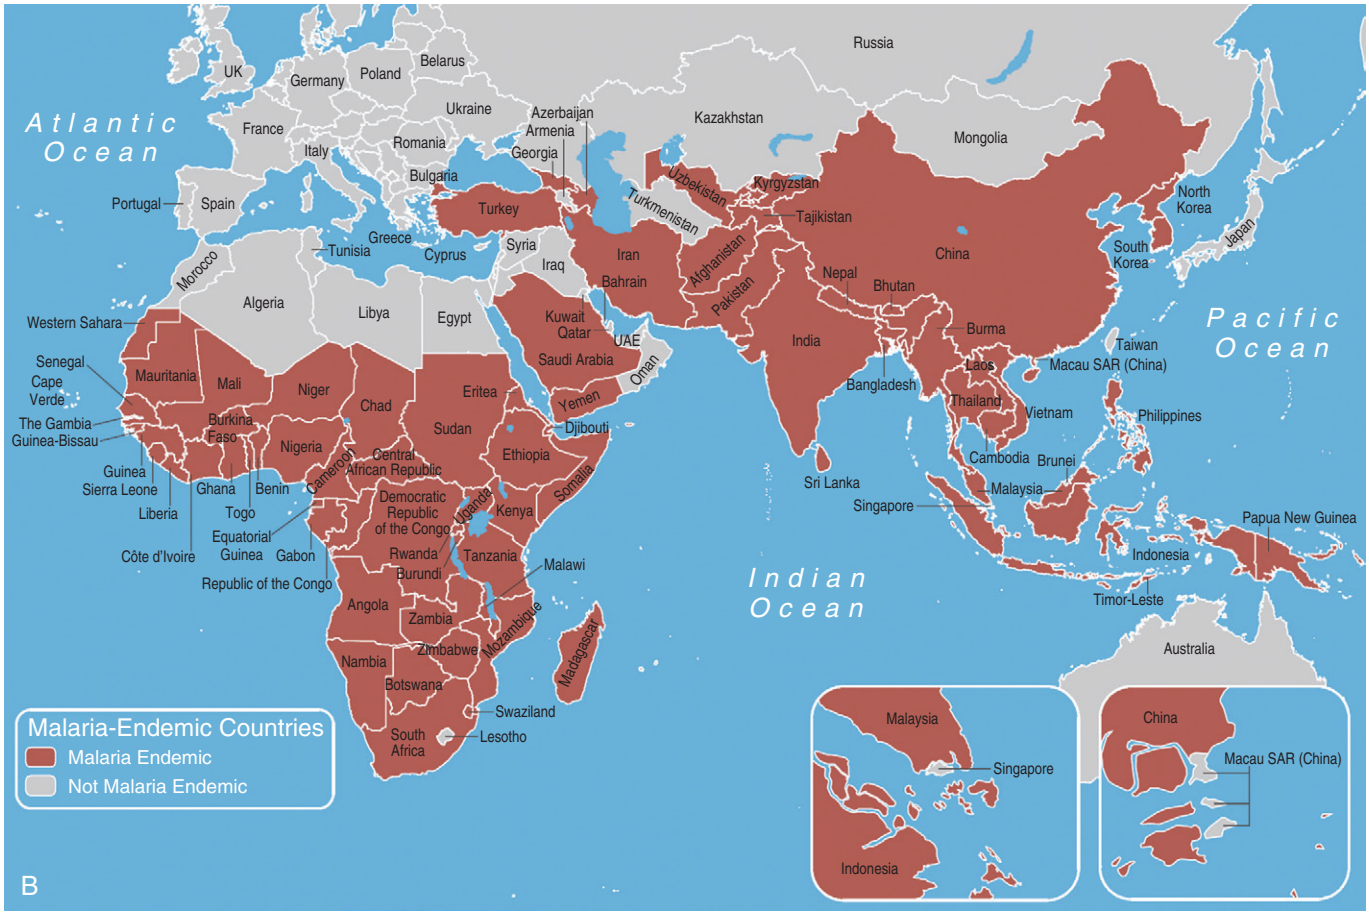

FIGURE 219-2, Cont'd

Cryptic Malaria

The category of cryptic malaria includes cases for which no source of infection can be identified. Typical cases include confirmed malaria in U.S. residents who have never traveled to or resided in malarial areas, who have not received blood transfusions, and who are not linked epidemiologically with other cases.[15,78,163] Airport malaria, one kind of cryptic malaria, occurs in proximity to international airports and is thought to occur when mosquitoes arriving with airplanes from endemic areas infect individuals working in or living near airports.[72]

HOST-PARASITE INTERACTION

The intensity of transmission of malaria depends on factors that affect the density of vectors and the extent of vector-human contact. Transmission of malaria may be continuous or seasonal, or it may depend on local site-specific factors, such as the presence of irrigation projects or intermittent flooding. Mosquito vectors differ in their efficiency in transmitting malaria; the principal vector in sub-Saharan Africa, *Anopheles gambiense*, is known for being a highly effective vector. Variations in climate may affect the viability of mosquitoes.

The incidence and severity of malaria are affected by the intensity of exposure, the presence of immunity, and genetic factors. Distinction must be made between malaria infection (presence of parasitemia) and malaria illness. A major puzzle in malaria is why individuals with similar degrees of parasitemia may exhibit radically different clinical manifestations.

Individuals who reside in endemic areas and are exposed continually to infected mosquitoes acquire some degree of immunity to malaria illness. Adults in these areas continue to become infected, but they have lower levels of parasitemia. Infants born to mothers with acquired immunity may be protected transiently by placental passage of maternal antibody. The highest incidence of infection with malaria occurs in infants and young children who are no longer protected by maternal antibody but who are too young for significant acquired immunity to have developed. Children also are more susceptible to certain manifestations of severe illness, such as cerebral malaria. The lack of acquired immunity in infants and young children accounts partly for their increased risk for acquiring disease and having severe manifestations. Acquired immunity diminishes during pregnancy, and pregnant women are at high risk for development of severe complications of malaria. Individuals in the population who remain asymptomatic but harbor gametocytes in their blood are reservoirs of infection when bitten by mosquitoes. With the exception of *P. knowlesi*, which infects monkeys, there are no significant animal reservoirs of malaria.

Clinical manifestations of malaria may be severe in nonimmune patients. Malaria is the most common life-threatening infection acquired by travelers to malaria-endemic regions. Individuals with acquired immunity who then leave endemic areas for long periods may lose their immunity and be at risk for severe disease if reexposed.

Genetic factors determine the risk for acquiring malaria and having severe infection. Individuals who have a Duffy-negative blood type lack the most important specific receptors for invasion of the merozoites of *P. vivax*, and these individuals have markedly reduced susceptibility to infection with this species.[73,100] This resistance is the basis for the low incidence of vivax malaria in Africa. Specific human leukocyte antigens present in individuals from West Africa may protect against the development of severe complications of malaria, including cerebral malaria and severe anemia. The best-known example of the relationship between malaria and genetics is the association between sickle hemoglobinopathies and protection against severe falciparum malaria. This balanced polymorphism is thought to have helped ensure survival of the gene for hemoglobin S in the population because of the selective advantage provided on a population basis to those who are heterozygous for sickle-cell disease. Individuals with sickle hemoglobinopathies still may be infected and manifest signs and symptoms of malaria, although the risk for acquiring severe malaria or dying of malaria may be 60-fold to 70-fold less in children with hemoglobin AS than in children with hemoglobin AA.[75]

PATHOPHYSIOLOGY

Pathophysiologic changes in malaria are caused by destruction of RBCs, production of cytokines, stimulation of intravascular synthesis of nitric oxide, and sequestration of infected erythrocytes.

Lysis of RBCs leads to anemia, which may be severe, and its attendant hemodynamic consequences. Anemia may develop as a result of hemolysis, impaired erythropoiesis, or bone marrow depression secondary to folic acid deficiency.[119] Intravascular hemolysis may be so severe that it results in pronounced hemoglobinuria (blackwater fever), which may be a precipitating event in the development of renal failure. This complication has been noted in association with treatment using quinine. Hematopoiesis is suppressed during acute infection, and such suppression may not be reversed as readily in iron-deficient individuals, contributing to chronic anemia.

Cytokines such as tumor necrosis factor (TNF) and interleukin-1 have important roles in the pathogenesis of malaria.[10,76] Severe disease has been associated with higher concentrations of TNF, and TNF polymorphisms may play a role in the development of specific complications.[95,96] Parasite factors responsible for release of cytokines have not been identified. A possible mechanism for the role of TNF in malaria pathogenesis is that the binding of TNF to its receptors is known to cause signaling to amplify cytokines of inflammatory cascades.[125] Another possible role of TNF in malaria is to stimulate nitric oxide, a short-lived neurotransmitter. Nitric oxide may have a role in cerebral malaria, and its transient nature may provide a partial explanation for the complete recovery noted in some patients with severe cerebral malaria. TNF and nitric oxide have harmful and beneficial roles in the pathogenesis of malaria; both have been shown to be correlated with clearance of parasites and eventual recovery and the severity of illness.

Sequestration of infected RBCs has long been thought to contribute to the clinical manifestations of malaria, particularly that caused by *P. falciparum*. Late-stage parasites induce host cells to develop knobs on the surface of erythrocytes that facilitate adherence of these cells to vascular endothelium. The effects of these sequestered RBCs on the perfusion, nutrition, and oxygenation of surrounding tissues may be responsible for the complications of *P. falciparum* infection, including cerebral malaria, renal failure, and watery diarrhea.[106,122] Consumption of glucose by metabolically active late-stage parasites contributes to hypoglycemia and lactic acidosis. Despite these changes, the majority of histopathologic appearances of tissue is remarkably benign, consistent with the reversible nature of the changes and supportive of the role of cytokines and secondary messengers in the pathogenesis of complications of cerebral malaria.[75,150] Recent postmortem microscopy of brain sections from adults who died of malaria confirmed that sequestration of cerebral microvasculature was significantly higher in patients with cerebral malaria and was also correlated with deeper levels of premortem coma and shorter time to death.[123]

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

The clinical manifestations of malaria depend on the species of malaria parasite causing the infection, the immune status of the individual, the mode of transmission of infection, whether the individual was taking prophylaxis, and host immune factors (Table 219-1). Acute malaria generally is understood to refer to the signs and symptoms associated with disease caused by infection with malaria parasites.

Recurrent infections are of three types: relapse, recrudescence, and reinfection. Relapses occur as a result of delayed maturation of the dormant liver stages (hypnozoites) of *P. vivax* or *P. ovale*. Recrudescence occurs when parasitemia caused by the same parasite responsible for the initial infection recurs after clearance or a significant reduction in the initial parasitemia. It occurs most commonly with *P. falciparum* because of drug resistance. Reinfection with different parasites and infection with more than one type of *Plasmodium* occur especially in areas with a high intensity of transmission. Persistent infection is noted with *P. malariae*. Hypnozoites have not been identified with *P. malariae*, so the organism is thought to persist as a low-level parasitemia that can exist for years without causing symptoms.

A classic description of malaria includes features of the malaria paroxysm resulting from the lysis of parasitized RBCs and release of merozoites into the circulation at

TABLE 219-1 **Characteristics of the *Plasmodium* Species Responsible for Human Malaria**

Characteristic	Species				
	P. FALCIPARUM	*P. VIVAX*	*P. OVALE*	*P. MALARIAE*	*P. KNOWLESI*
Incubation period in days (range)	12 (8-25)	14 (8-27)	17 (15-≥18)	28 (15-≥40)	11 (9->12)
Periodicity of febrile attacks (hr)	None	48	48	72	24
Earliest appearance of gametocytes (days)	10	3	?	?	?
Relapse	No	Yes	Yes	No	No
Duration of untreated infection (yr)	1-2	1.5-4	1.5-4	3-50	?

RBC, Red blood cell.

the completion of asexual reproduction. The paroxysm is characterized by fever and chills accompanied by constitutional symptoms of headache, body ache, fatigue, dizziness, and malaise. Gastrointestinal symptoms include nausea and vomiting, abdominal pain, and diarrhea. Cough and dyspnea may accompany an attack. Although periodicity of the paroxysms in primary attacks is thought to be pathognomonic for malaria species, this periodicity may take several days to become established, may not occur at all in asynchronous infections, or may be modified by previous immunity or treatment.

In children, fever and headache may be the sole symptoms or gastrointestinal symptoms may predominate. Physical signs of malaria include pallor, jaundice, and hepatosplenomegaly. Rash and lymphadenopathy typically are not associated with malaria, although malaria may precipitate recrudescence of latent herpes infections.

Anemia is the most common abnormality in malaria. Thrombocytopenia is common and may be the first manifestation in patients with uncomplicated malaria.[75] Leukopenia also may occur, but high white blood cell counts are less usual and should provoke investigation for other conditions. Liver function test abnormalities may be present and can be mistaken for evidence of hepatitis, especially in patients with jaundice and tender hepatosplenomegaly. Hypoglycemia occurs frequently with falciparum malaria and may develop before or as a consequence of treatment with quinine. When present in children before treatment, hypoglycemia is associated with a poor prognosis.[149] Hyponatremia may occur as part of the syndrome of inappropriate secretion of antidiuretic hormone in some patients. Serum creatinine and blood urea nitrogen values may be elevated transiently or may increase significantly with acute renal failure.

Malaria stimulates a polyclonal increase in immunoglobulins associated with rapid production of malaria-specific antibodies and reduced complement levels. False-positive tests for syphilis, rheumatoid factor, heterophil agglutinins, and cold agglutinins may occur.[150]

Severe and Complicated Malaria

Nonimmune individuals are most susceptible to the severe complications of falciparum malaria, which include cerebral malaria, pulmonary failure or acute respiratory distress syndrome, renal failure, and severe anemia.[85] Hypoglycemia and metabolic acidosis may occur. Falciparum malaria in nonimmune patients should be considered a medical emergency, and treatment of *P. falciparum* should be initiated in all ill patients with malaria until the species can be confirmed. The highest mortality is seen in subjects who have a combination of severe respiratory distress, impaired consciousness, and severe anemia. The Centers for Disease Control and Prevention (CDC) and WHO criteria for the diagnosis of severe malaria are outlined in Table 219-2.

Severe Anemia

Children younger than 1 year old, especially in sub-Saharan Africa, are those most likely to experience severe malarial anemia. This complication is thought to occur most often in areas with year-round transmission. Clinical consequences of anemia are determined by rate of development of anemia and by severity of anemia, with high risk for complications as hemoglobin decreases to less than 5 g/dL.[160]

TABLE 219-2 **Manifestations of Severe Malaria**

Centers for Disease Control Definition*	World Health Organization Definition[165]
Cerebral malaria	Prostration, impaired consciousness, coma (cerebral malaria) or multiple convulsions
Severe anemia	Severe anemia
Acute renal failure	Renal impairment
Hemoglobinuria	Hemoglobinuria
Hypoglycemia	Hypoglycemia (<40 mg/dL)
Metabolic acidosis	Acidosis or hyperlactatemia
Hypotension caused by cardiovascular collapse	Circulatory collapse or shock
Acute respiratory distress syndrome	Respiratory distress or pulmonary edema
Coagulopathy	Abnormal bleeding
Hyperparasitemia (>5% infected RBCs)	Hyperparasitemia (>2% infected RBCs in low-transmission areas or >5% in high-transmission areas
	Jaundice
	Failure to feed

*From www.cdc.gov/malaria/about/disease/html#severe.
RBCs, Red blood cells.

Hypoglycemia

Hypoglycemia (blood glucose <40 mg/dL) may be present on initial evaluation in 20 percent of children with severe malaria and is associated with a poor prognosis. The etiology of pretreatment hypoglycemia is thought to be a combination of parasite consumption of glucose and inadequate gluconeogenesis in the liver. Hypoglycemia also can occur as a result of treatment, most typically with quinine. Intravenous or oral administration of quinine may lead to hypoglycemia by stimulating insulin secretion. Pregnant women seem to be especially susceptible to this complication.

Acid-Base Changes

Metabolic acidosis is a marker of severity and clinically may be manifested as hyperpnea. Acidosis often is associated with hypoglycemia. Fluid resuscitation and treatment with antimalarial drugs often result in rapid resolution of acidosis, although persistence of acidosis may occur in patients who eventually die of malaria.

Renal Complications

Acute renal failure is a potentially life-threatening consequence of acute malaria that occurs more commonly in adults than in children. It typically is oliguric and often is reversible if the patient can be supported by dialysis through the oliguric phase. Acute renal failure is a rare development in residents of endemic areas and long has been thought to occur more frequently in patients treated with quinine or quinidine (blackwater fever). The histologic changes resemble those of acute tubular necrosis.

Nephrotic syndrome and chronic renal failure occur more frequently in areas where malaria is endemic and usually are associated with infection with *P. malariae.* Symptoms occur in individuals younger than 15 years old in approximately half the cases, with gradual progression to renal failure over 3 to 5 years. Most patients have asymptomatic proteinuria and the gradual development of hypertension and deterioration in renal function. Adults more commonly have hematuria and azotemia; adults and children may have hematuria. The disease does not respond to antimalarial agents. Treatment with corticosteroids, cyclophosphamide, and azathioprine has had variable results, with remission occurring only in patients with mild changes on renal biopsy.[150]

Respiratory Complications

Pulmonary edema typically develops late in the course of severe malaria when other complications are already present, and it may occur when parasitemia has resolved and the patient appears to be clinically improving. Pulmonary edema occurs more commonly in adults than in children. The pathogenesis is consistent with capillary leak syndrome. Supplemental oxygen or mechanical ventilation with positive end-expiratory pressure may be necessary to manage respiratory complications. Because of the presence of alveolar macrophages, there is a well-characterized pulmonary inflammatory response that leads to respiratory distress in severe malaria.[113] Respiratory distress is the most dangerous presentation of severe malaria, especially in combination with severe anemia and cerebral malaria.[49]

Cerebral Malaria

Cerebral malaria is the most common complication of falciparum malaria in children and occurs most often in children 3 to 6 years old.[63,120] In general, it presents as alteration of consciousness and diffuse encephalopathy with prolonged multiple seizures in a patient with no other explanation for the condition. Patients may be comatose without response to stimuli and may assume an opisthotonic posture. Generalized convulsions may occur, but focal findings are uncommon. Serial electroencephalographic monitoring of 65 Kenyan children uncovered a large range of clinical and electrographic seizures with diffuse background slow wave activity, which are nonspecific features; electrical seizure activity consistently arose from the posterior temporoparietal region.[28] Intracranial pressure often is increased in children with cerebral malaria, but a relationship between the presence of increased intracranial pressure and morbidity and mortality has not been established. Factors associated with neurologic sequelae include prolonged coma, severe anemia, and multiple seizures. Mortality rates range from 15 to 30 percent of affected children; most survivors recover completely, but approximately 10 percent may have neurologic sequelae. The most common neurologic sequelae in children noted in a study in the Gambia were hemiplegia, cortical blindness, aphasia, and ataxia.[14]

Many factors, including hypoglycemia, anemia, microvascular obstruction, acidosis, and elaboration of inflammatory mediators, contribute to the syndrome of cerebral malaria. Histopathologic features are minor, with occasional hemorrhages and perivascular infiltrates.

Hyperreactive Malarial Syndrome (Tropical Splenomegaly Syndrome, Hyperreactive Malarial Splenomegaly)

Hyperreactive malarial syndrome is characterized by massive splenomegaly, high concentrations of total serum IgM and malarial antibodies of multiple immunoglobulin classes, and clinical and immunologic response to antimalarial agents.[170] Hyperreactive malarial syndrome is correlated with malaria endemicity, with an incidence ranging from 0.5 to 80 percent of the adult population. The pathogenesis is unknown but seems to involve chronic exposure to malaria, resulting in chronic stimulation of the immune system and genetic factors. Findings on physical examination include a huge spleen (>10 cm below the costal margin) and an enlarged liver. Laboratory findings include anemia and an increased reticulocyte count, elevated IgM (>2 standard deviations above the mean), and high antibody levels of antimalarial antibodies.[143] Some patients may have thrombocytopenia or neutropenia. Patients may have an increased risk for acquiring bacterial infections, and some researchers have suggested that hyperreactive malarial syndrome is a premalignant condition.[7] Lifelong treatment with antimalarial agents is the treatment of choice for patients who reside in endemic areas.[150] Treatment of patients who have left endemic areas has not been standardized; a publication including several case reports shows success with a single treatment course of antimalarial agents followed by close monitoring of the size of the spleen.[143]

MALARIA IN SPECIAL POPULATIONS

Malaria in Children

The signs and symptoms of malaria in children range from asymptomatic infection to life-threatening illness. Severe anemia is most likely to develop in children younger than 2 years old, whereas cerebral malaria is most likely to occur in older children (mean age 3.5 years). The greatest burden of disease is borne by infants and young children, although the impact of disease on adolescents has not been studied extensively. Malaria in pregnant adolescents may be of particular concern.[77]

In endemic areas, lack of diagnostic facilities, limited resources, and encroaching drug resistance complicate the ability to make a rapid, accurate diagnosis and provide expedient treatment to children with malaria. Malaria often is difficult to distinguish from other common illnesses such as pneumonia. Clinical algorithms that can distinguish children with malaria from children with pneumonia or other illnesses have been developed and studied but do not eliminate completely the overlap with conditions having similar clinical manifestations.[126,127,133] Risk factors for a fatal outcome in children with malaria were studied in Kenya; the presence of coma or respiratory distress, or both, at initial evaluation identified children at high risk for dying.[92,49]

Imported malaria occurs in children in many nonendemic countries. The diagnosis often is delayed because of lack of consideration of malaria as a cause of illness and unfamiliarity with the disease. In children with acquired immunity, the signs and symptoms of disease may be subtle and nonspecific but fever or a history of fever is universal.[36,84] Other symptoms include anorexia, vomiting, diarrhea, headache, lethargy, and abdominal pain. Laboratory findings include anemia, thrombocytopenia, and leukopenia. The diagnosis of malaria should be considered in every child with fever or a history of recent fever who has visited an area where malaria occurs.

Congenital Malaria

All four types of human malaria can be transmitted congenitally, but the disease most often is associated with *P. vivax*. Congenital malaria has not been reported with *P. knowlesi*. That congenital malaria is not seen more frequently is due partly to the effective barrier function of the placenta. Congenital malaria develops in infants of approximately 0.1 percent of immune mothers and 10 percent of nonimmune mothers in endemic areas, although placental infection occurs in one third of pregnant women.[67] In endemic areas, distinguishing malaria acquired congenitally from malaria acquired by transmission from mosquitoes is difficult. In non–malaria-endemic countries, congenital malaria is very rare; five cases have been reported in the United States since 2000.[18]

The onset of symptoms is insidious and usually occurs at 2 to 8 weeks of age. The typical malaria paroxysm is absent, with the infant instead having poor feeding, fever, vomiting, diarrhea, irritability, and hepatosplenomegaly on physical examination.[61] The most common laboratory finding is anemia, but thrombocytopenia and hyperbilirubinemia also occur. Therapy for the infecting species of malaria is curative, and the infant does not need treatment of the exoerythrocytic stages of the parasite (although the mother does).

Malaria in Pregnancy

The effects of malaria on the mother depend on the degree of immunity that she has attained and her parity.[99] Relapses and recrudescence of malaria are common during pregnancy, probably because of the immunosuppression associated with the pregnant state. Malaria can exacerbate the anemia occurring during pregnancy, and hypoglycemia and renal insufficiency may complicate falciparum malaria during pregnancy.[48]

Placental infection during pregnancy may be associated with low birth-weight, particularly in primigravidas. Vivax malaria has been linked to maternal anemia and low birth-weight in multigravidas and primigravidas.[109] Severe falciparum malaria is harmful to the fetus because of fetal tachycardia and distress secondary to maternal fever; disruption of maternal-fetal blood flow and exchange of metabolic substrates by malaria parasites trapped in the placenta; and the potential for reduction in fetal glucose supply, which may be exacerbated by treatment with quinine, a drug that is able to stimulate the release of insulin.[82] Heavy infection of the placenta interferes with transfer of tetanus antibodies from the mother to the fetus, but the effect on other antibodies is unknown.[13]

Prompt treatment of pregnant women with severe malaria is critical to survival of the mother and the fetus.

DIAGNOSIS

The most important first step in establishing the diagnosis of malaria is to consider the diagnosis in all individuals with febrile illness, especially febrile individuals with a history of travel to endemic areas. Having a high index of suspicion for the diagnosis of malaria cannot be overemphasized. Failure to diagnose and treat malaria promptly contributed to fatal outcomes in U.S. civilians who died of malaria between 1963 and 2001.[107] In one series of fatal falciparum malaria cases in the United States, 40 percent of patients were not recognized as having malaria during their initial contact with a physician.[46] Manifestations of the disease are most classic in nonimmune individuals or in individuals in areas where malaria transmission is seasonal. Signs and symptoms of disease may be nonspecific in semi-immune individuals, those who have received malaria prophylaxis, or individuals who have been partially treated.

In nonendemic areas, a history of travel to an endemic area should suggest the diagnosis in all individuals with a febrile illness, regardless of the accompanying signs and symptoms.[164] Common diagnoses mistakenly assigned to patients ultimately determined to have malaria include gastroenteritis and viral syndrome. The course of disease may be modified by exposure to antimalarial drugs, such as agents that may have been used for prophylaxis, and the incubation period may be prolonged after the administration of antimalarial chemoprophylaxis. Because malaria may be transmitted by blood transfusion or an organ transplant, may be congenitally acquired, and, rarely, occurs cryptically, the diagnosis also should be considered in patients with compatible signs and symptoms of malaria, anemia, or thrombocytopenia and no other explanation for their illness.

Microscopy is the technique used most commonly for establishing the diagnosis of malaria. Rapid diagnostic tests to detect parasite antigens are important tools in centers lacking expertise in malaria diagnostic microscopy. Other alternatives to microscopic diagnostic techniques for malaria include tests using fluorescent microscopy, DNA probes, polymerase chain reaction (PCR), antibody detection, and flow cytometry. Only a few of these methods meet the requirements of low cost, high reliability and reproducibility, and rapid turnaround time. Some of them are suitable for use in field conditions, however, and have been used in endemic areas and for self-diagnosis.

Diagnosis of cerebral malaria is largely clinical. Patients with cerebral malaria typically do not have marked cerebrospinal fluid (CSF) pleocytosis, differentiating this entity from bacterial meningitis. In comparing CSF parameters in children with cerebral malaria to those with viral encephalitis, those with cerebral malaria have a lower CSF glucose level and higher protein and lactate dehydrogenase (LDH) levels, CSF-to-blood LDH ratio, and CSF-to-serum adenosine deaminase ratio.[65]

Microscopy

Microscopy is the gold standard for establishing the diagnosis of malaria. Identification of typical parasite forms by an experienced microscopist is the mainstay of diagnosis worldwide (Figs. 219-3 through 219-7). There are many advantages of using light microscopy: it can be performed at low cost, it can be done rapidly, it allows identification of the infecting species and estimation of parasite load, and it can be performed with a small sample of blood. The major disadvantage of microscopy is the need for an experienced microscopist. In settings where malaria is not endemic, the need for specialists to review microscope slides may lead to a delay in establishing the diagnosis.

Thin smears are the most useful in diagnosing malaria. They are easy to prepare, with only a single drop of blood required. The drop of blood is placed at one end of the slide, and the edge of a second slide is placed at the edge of the blood smear and drawn across the slide.[114] RBC morphology is preserved by methanol fixation, so invasion of large RBCs by the parasites can be identified and speciation of the organism is possible (see Table 219-1). Oil-immersion magnification (1000×) should be used for viewing the slide because many young asexual intraerythrocytic parasites are only 2 to 3 μm in diameter and may be missed when using high-dry (440×) magnification. The microscopist begins by looking at the thin edge of the blood film farthest from where the drop of blood was placed. Giemsa stain is preferred to Wright stain when available because it preserves details such as Schüffner dots in *P. vivax* and *P. ovale* infections. When individual RBCs can be seen at low magnification (100×), switching to oil immersion allows examination for parasites within the cells. The major disadvantage of thin films is low sensitivity. With low parasite loads (<100 to 300/μL), the amount of blood on the smear may be too small to detect the parasites.

Thick smears have greater sensitivity than thin smears as a result of the larger quantity of blood used. Because the RBCs are lysed during preparation of the slide, the types of cells containing parasites cannot be identified. To make a thick smear, a drop of blood is placed on the slide and spread in a circle. The slide is stained without using methanol fixation so that RBCs lyse.

Estimating parasite density is useful for assessing parasite density and for evaluating response to therapy. The density of parasites can be determined on thick or thin smears.[75] When thin smears are used, the proportion of RBCs infected is counted while the smear is viewed under an oil-immersion lens.

Fluorescent Microscopy

The quantitative Buffy coat test relies on identification of parasitized RBCs stained with acridine orange in the RBC layer of centrifuged blood.[147] Experienced personnel can perform the test rapidly, but the reagents are costly when compared with those needed for microscopy and the species of parasite cannot be identified. If a fluorescent microscope is available, identification of

parasitized RBCs can be accomplished by staining a thick smear with acridine orange and examining it under fluorescent light.

Detection of Parasite Antigen

Antigen capture dipstick assays based on detection of histidine-rich protein 2 (HRP-2) (ParaSight F), HRP-2 and aldolase (ICT Malaria Pf/Pv), or parasite LDH (OptiMAL-IT) have been developed.[33,86,102] These assays use a finger-prick sample of blood and give a result in 10 to 15 minutes. Assays detecting HRP-2 are specific for *P. falciparum*, whereas assays based on parasite LDH or HRP-2 and aldolase can identify four species of *Plasmodium*.[30,102] The Binax Now malaria test, based on detection of a pan-malaria antigen and a circulating antigen specific to *P. falciparum*, was licensed in the United States in 2007.[40] The ParaSight F dipstick test, when studied in field trials in Kenya, showed a sensitivity of 96.5 to 100 percent in patients whose parasitemia was greater than 60 parasites/μL, with lower sensitivity noted at lower levels of parasitemia. Antigen persisted to day 6 in 11.9 percent of children whose blood smears were clear at that time.[8] When studied in travelers, the sensitivity of the ParaSight F test ranged from 40 percent in subjects with less than 50 parasites/μL to 93 percent or more in subjects with more than 100 parasites/μL, and positive dipstick tests occurred in 68 percent of blood smear–negative patients on day 7 and in 20 percent on day 28.[62]

Compared with the PCR assay, the HRP-2 assays performed well, with sensitivity of 88 to 95 percent and specificity of 95 to 97 percent; when the HRP-2 assays were compared with microscopy, sensitivity ranged from 80 to 95 percent and specificity ranged from 85 to 100 percent.[114] The tests also performed well when used in nonimmune travelers; a meta-analysis of 21 studies identified sensitivity of 88 to 98 percent and specificity of 95 to 100 percent for detection of *P. falciparum*.[94] The HRP-2/aldolase-based assay that can detect four species of malaria has a lower sensitivity for diagnosis of vivax malaria, although this assay has a higher sensitivity for detection of malaria than the HRP-2 assay.[25,64,102] A limitation of HRP-2–based assays is that they remain positive after therapy because HRP persists in the blood after acute infection.

LDH-based assays are able to distinguish between *P. falciparum* and other malaria species, although the test is unreliable in detecting *P. vivax* in the presence of *P. falciparum*.[124] Sensitivity of OptiMAL-IT was 85 to 95 percent, with specificity of nearly 100 percent for *P. falciparum* and 75 to 85 percent for *P. vivax*. The Clearview malaria test has an overall sensitivity of 93 percent and specificity of 100 percent, with sensitivities of 99, 90.0, 86, and 60 percent, respectively, for *P. falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*.[60] For both OptiMAL-IT and the Clearview malaria tests, sensitivity decreased with decreasing parasite density. An advantage of LDH-based assays is the ability to distinguish between viable and nonviable parasites, rendering the test useful for monitoring response to therapy.[23,26,64,102,117]

Dipstick tests may have a role in cost-effective diagnosis of malaria in situations in which laboratory services are inadequate, in mobile clinics, in locations where levels of malaria transmission are low and drug resistance is high, when the cost of treatment exceeds the cost of the dipstick test, and when blood smears are negative and determining the diagnosis is critical. In developed countries, dipstick assays would benefit laboratories with less experienced microscopists by helping them establish a rapid diagnosis, confirm a diagnosis made by microscopy, or determine the infecting species. Current limitations of the tests are decreased sensitivity compared with expert microscopy, especially at low levels of parasite density; cost; and lack of approval by the U.S. Food and Drug Administration (FDA) of some of the tests.

Dipstick malaria tests have been proposed for use by travelers for self-diagnosis of malaria and have been tested for this purpose. The accuracy of both test performance and interpretation of results by travelers has not been demonstrated as high enough to recommend this strategy routinely for travelers. Most experts suggest using the test to guide initial treatment while the traveler is heading to a source of health care for more definitive diagnosis and treatment.[66,108]

DNA Probe

Specific DNA probes for identification of *P. falciparum* have been developed and tested in field conditions in Thailand.[5] The technique compared favorably with microscopy and could be used to test large numbers of samples at a time, but it had the disadvantage of needing a radiolabeled probe. Nonisotope probes have been used in other field trials in Madagascar, where an enzyme-linked probe was compared with microscopy for diagnosis of falciparum malaria. Results were comparable to examination of thick smears by microscopy for *P. falciparum* infection, but the assay could not identify infection with *P. vivax*, *P. ovale*, or *P. malariae* alone.[97]

Polymerase Chain Reaction Assay

PCR-based techniques used for establishing the diagnosis of malaria are highly sensitive and now are able to detect mixed infections. Compared with thick and thin smears, sensitivity and specificity are nearly 100 percent. PCR techniques can be useful for determining the species of an infection when microscopy is equivocal. Early detection of resistance to antimalarial drugs is another benefit of PCR-based techniques, which have been used to detect a mutation of *P. falciparum* associated with resistance to chloroquine.[39,69] Currently, PCR is the only definite and validated means of diagnosing *P. knowlesi*, because this species may be confused with *P. malariae* on microscopy.[167]

Major disadvantages of the PCR assay include the need for expensive equipment, reagents, and significant technical expertise and the length of time required to perform the testing. At this time, the PCR assay may be better suited for use in large-scale epidemiologic surveys, rather than for establishing the diagnosis of acute malaria in the clinical setting.

Flow Cytometry

Automated blood cell analyzers based on flow cytometry have been shown to display cells containing malaria pigment as a population of cells distinct from other blood components. To date, this discovery has been serendipitous in patients not suspected to have malaria and the diagnosis must be confirmed by conventional methods.[51,70] A future application of this technology could be to modify automated blood cell analyzers to flag specimens that need to be examined further by thin or thick smears (or both).[70]

Antibody Detection

Malaria antibodies develop rapidly after infection and remain present for years; they are of limited value in diagnosing malaria in individual patients. Occasionally, antibody tests might prove useful in the diagnosis of nonimmune individuals with cryptic febrile illnesses or on a population basis to assess the degree of community-wide immunity. Measurement of antibody may have a role in the diagnosis of hyperreactive malarial syndrome.[170]

TREATMENT

Treatment of malaria depends on identification of the species of *Plasmodium* causing infection, knowledge of the presence of resistance to chloroquine and other drugs in the area in which malaria was contracted, and therapeutic goals (treatment of acute illness, eradication of the exoerythrocytic phase of malaria, or prevention of infection). Drugs and classes of drugs currently in use for treating malaria include 4-aminoquinolines and related compounds (chloroquine, mefloquine [Lariam], amodiaquine); primaquine; sulfadoxine-pyrimethamine (Fansidar); halofantrine; atovaquone-proguanil (Malarone); artemisinin (qinghaosu) and other artemisinins (artemether, artesunate) and artemisinin drugs in combination with other agents; cinchona alkaloids (quinine, quinidine); and the antimicrobial agents doxycycline, tetracycline, and clindamycin. Investigational compounds and combination drugs are in various stages of development. Drugs that may be used for the treatment of malaria in the United States are listed in Table 219-3. Drugs used for the prevention of malaria are discussed in a subsequent section.

The choice of agent to treat symptomatic malaria depends on the presence of resistance to chloroquine and other antimalarial drugs, the availability of drugs in the local area, and the age of the patient. Local and national guidelines for the treatment of malaria differ, and practitioners treating patients with malaria should consult local resources and experts. Country-specific information on the local areas with malaria, the estimated risk for malaria, whether there is chloroquine-resistant malaria, and which malaria species are present is available in the United States from the CDC* and outside the United States from local and national health organizations and the WHO.*

In malaria-endemic areas, strategies such as intermittent treatment of infants and pregnant women are being employed in combination with use of insecticides and treated bed nets to prevent and treat malaria.[136] A full discussion of these programs is beyond the scope of this chapter.

Antimalarial Agents Available for Use in the United States

Chloroquine

Chloroquine is the drug of choice for chloroquine-susceptible malaria caused by *P. falciparum* and *P. vivax* and for all infections with *P. ovale* and *P. malariae*. Chloroquine is a 4-aminoquinoline with rapid schizonticidal activity. It is not effective against exoerythrocytic forms of the parasite, and patients treated with chloroquine after acquiring *P. vivax* or *P. ovale* infection need to have additional treatment to eliminate these forms. Chloroquine is most active against late ring stages and mature trophozoites. Response to treatment is rapid, with disappearance of parasitemia within 48 to 72 hours after initiation of treatment when the parasite is susceptible.

Chloroquine is available as an oral preparation and, in many areas, as intramuscular and intravascular formulations. Oral absorption is excellent, and the drug is safe and effective when given by nasogastric or orogastric tube in comatose children.[161] Intramuscular and intravenous administration may be associated with an increased risk for cardiac arrhythmias.

Adverse reactions to chloroquine rarely occur at the doses used for suppression or treatment of malaria. Side effects include gastrointestinal symptoms such as nausea, vomiting, and diarrhea; dizziness; headache; and fatigue. Pruritus may be a troubling adverse event, especially in black patients. Chloroquine has no known teratogenic effects, and it may be used in pregnant and lactating women. The drug is not contraindicated in glucose-6-phosphate dehydrogenase (G6PD)–deficient individuals. Serious adverse events, including hypotension, cardiac arrest, and circulatory failure, may occur after intravenous or intramuscular use of the drug, especially in children. Psychotic symptoms may occur rarely with chloroquine.[44] Chloroquine always should be given slowly when administered intravenously and in small doses when given by intramuscular injection; some experts discourage the parenteral administration of chloroquine. Oral doses are absorbed rapidly. The risk for aspiration occurring while giving a dose by tube to a comatose patient must be weighed against the risk for delaying therapy if parenteral treatment is unavailable or of complications developing when giving chloroquine by the intravenous or intramuscular route. The lethal dose of chloroquine is 1 g in children and 4 g in adults. Cumulative doses exceeding 100 g are associated with an increased

Mefloquine plus primaquine phosphate[9] Mefloquine: treatment as above Primaquine phosphate: treatment as above	**A. Quinine sulfate plus either doxycycline[6] or tetracycline[6] plus primaquine phosphate[9]** **Quinine sulfate:** treatment as above **Doxycycline or tetracycline:** treatment as above **Primaquine phosphate:** treatment as above B. Atovaquone-proguanil plus primaquine phosphate[9] Atovaquone-proguanil: treatment as above Primaquine phosphate: treatment as above C. Mefloquine plus Primaquine phosphate[9] Mefloquine: treatment as above Primaquine phosphate: treatment as above
Uncomplicated malaria: alternatives for pregnant women[11,12,13]	**Chloroquine-sensitive** (see uncomplicated malaria sections above for chloroquine-sensitive species by region)	**Chloroquine phosphate:** treatment as above *or* **Hydroxychloroquine:** treatment as above	Not applicable
	Chloroquine-resistant (see sections above for regions with chloroquine-resistant *P. falciparum* and *P. vivax*)	**Quinine sulfate plus clindamycin** **Quinine sulfate:** treatment as above **Clindamycin:** treatment as above *or* **Mefloquine:** treatment as above	Not applicable

Severe malaria[14,15,16]	**All regions**	**Quinidine gluconate**[14] **plus one of the following: doxycycline**[4]**, tetracycline**[4]**, or clindamycin** **Quinidine gluconate:** 6.25 mg base/kg (= 10 mg salt/kg) loading dose IV over 1-2 hr, then 0.0125 mg base/kg/min (= 0.02 mg salt/kg/min) continuous infusion for at least 24 hr. An *alternative regimen* is 15 mg base/kg (= 24 mg salt/kg) loading dose IV infused over 4 hr, followed by 7.5 mg base/kg (= 12 mg salt/kg) infused over 4 hr every 8 hr, starting 8 hr after the loading dose (see package insert). Once parasite density <1% and patient can take oral medication, complete treatment with oral quinine, dose as above. Quinidine/quinine course = 7 days in Southeast Asia; = 3 days in Africa or South America. **Doxycycline:** treatment as above. If patient not able to take oral medication, give 100 mg IV every 12 hr and then switch to oral doxycycline (as above) as soon as patient can take oral medication. For IV use, avoid rapid administration. Treatment course = 7 days. **Tetracycline:** treatment as above **Clindamycin:** treatment as above. If patient not able to take oral medication, give 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 hr. Switch to oral clindamycin (oral dose as above) as soon as patient can take oral medication. For IV use, avoid rapid administration. Treatment course = 7 days. ***Investigational new drug (contact CDC for information):*** **artesunate followed by one of the following: atovaquone-proguanil (Malarone), doxycycline (clindamycin in pregnant women), or mefloquine**	**Quinidine gluconate**[14] **plus one of the following: doxycycline**[4]**, tetracycline**[4]**, or clindamycin** **Quinidine gluconate:** same mg/kg dosing and recommendations as for adults. **Doxycycline:** treatment as above. If patient not able to take oral medication, may give IV. For children <45 kg, give 2.2 mg/kg IV every 12 hr and then switch to oral doxycycline (dose as above) as soon as patient can take oral medication. For children >45 kg, use same dosing as for adults. For IV use, avoid rapid administration. Treatment course = 7 days. **Tetracycline:** treatment as above **Clindamycin:** treatment as above. If patient not able to take oral medication, give 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 hr. Switch to oral clindamycin (oral dose as above) as soon as patient can take oral medication. For IV use, avoid rapid administration. Treatment course = 7 days. ***Investigational new drug (contact CDC for information):*** **artesunate followed by one of the following: atovaquone-proguanil (Malarone), clindamycin, or mefloquine**

*Based on drugs currently available for use in the United States. If outside the United States, contact national authorities about current recommendations.

[†]*Note:* There are three options (A, B, or C) available for treatment of uncomplicated malaria caused by chloroquine-resistant *P. falciparum*. Options A and B are equally recommended. Because of a higher rate of severe neuropsychiatric reactions seen at treatment doses, we do not recommend option C (mefloquine) unless options A and B cannot be used. For option A, because there are more data on the efficacy of quinine in combination with doxycycline or tetracycline, these treatment combinations are generally preferred to quinine in combination with clindamycin.

[2]For infections acquired in Southeast Asia, quinine treatment should continue for 7 days. For infections acquired in Africa and South America, quinine treatment should continue for 3 days.

[3]U.S.-manufactured quinine sulfate capsule is in a 324-mg dosage; therefore, 2 capsules should be sufficient for adult dosing. Pediatric dosing may be difficult due to unavailability of noncapsule forms of quinine. If unable to provide pediatric doses of quinine, consider Malarone (recommendation B) or mefloquine (recommendation C).

[4]Doxycycline and tetracycline are not indicated for use in children younger than 8 years of age. For children younger than 8 years of age with chloroquine-resistant *P. falciparum* malaria, quinine (given alone for 7 days or given in combination with clindamycin) and atovaquone-proguanil are recommended treatment options; mefloquine can be considered if no other options are available. For children younger than 8 years of age with chloroquine-resistant *P. vivax* malaria, quinine (given alone for 7 days) or mefloquine is the recommended treatment option. If none of these treatment options is available or is not being tolerated and if the treatment benefits outweigh the risks, doxycycline or tetracycline may be given to children younger than 8 years of age.

[5]Give atovaquone-proguanil with food. If patient vomits within 30 minutes of taking a dose, then the dose should be repeated.

[6]Treatment with mefloquine is not recommended in persons who have acquired infections from the Southeast Asian region including Myanmar, Thailand, and Cambodia due to resistant strains.

[7]Primaquine is used to eradicate any hypnozoite forms that may remain dormant in the liver, and thus prevent relapses, in *P. vivax* and *P. ovale* infections. Because primaquine can cause hemolytic anemia in persons with G6PD deficiency, patients must be screened for G6PD deficiency before starting treatment with primaquine. For persons with borderline G6PD deficiency, or as an alternate to the above regimen, primaquine may be given 45 mg orally one time per week for 8 weeks; consultation with an expert in infectious disease and/or tropical medicine is advised if this alternative regimen is considered in G6PD-deficient persons. Primaquine must not be used during pregnancy.

[8]*Note:* There are two options (A or B) available for treatment of uncomplicated malaria caused by chloroquine-resistant *P. vivax*. High treatment failure rates due to chloroquine-resistant *P. vivax* have been well documented in Papua New Guinea and Indonesia. Rare case reports of chloroquine-resistant *P. vivax* malaria have also been documented in Burma (Myanmar), India, and Central and South America. Persons acquiring *P. vivax* infections outside Papua New Guinea or Indonesia should be started on chloroquine. If the patient does not respond, the treatment should be changed to a chloroquine-resistant *P. vivax* regimen and the CDC should be notified (Malaria Hotline number: 770-488-7788 or 770-488-7100). For treatment of chloroquine-resistant *P. vivax* infections, options A and B are equally recommended.

[9]For pregnant women diagnosed with uncomplicated malaria caused by chloroquine-resistant *P. falciparum* or chloroquine-resistant *P. vivax*, treatment with doxycycline or tetracycline is generally not indicated. However, doxycycline or tetracycline may be used in combination with quinine (as recommended for nonpregnant adults) if other treatment options are not available or are not being tolerated and if the benefit is judged to outweigh the risks.

[10]Because there are no adequate, well-controlled studies of atovaquone and/or proguanil hydrochloride in pregnant women, atovaquone-proguanil is generally not recommended for use in pregnant women. For pregnant women diagnosed with uncomplicated malaria caused by chloroquine-resistant *P. falciparum,* atovaquone-proguanil may be used if other treatment options are not available or are not being tolerated and if the potential benefit is judged to outweigh the potential risks. There are no data on the efficacy of atovaquone-proguanil in the treatment of chloroquine-resistant *P. vivax* infections.

[11]Because of a possible association with mefloquine treatment during pregnancy and an increase in stillbirths, mefloquine is generally not recommended for treatment in pregnant women. However, mefloquine may be used if it is the only treatment option available and if the potential benefit is judged to outweigh the potential risks.

[12]For *P. vivax* and *P. ovale* infections, primaquine phosphate for radical treatment of hypnozoites should not be given during pregnancy. Pregnant patients with *P. vivax* and *P. ovale* infections should be maintained on chloroquine prophylaxis for the duration of their pregnancy. The chemoprophylactic dose of chloroquine phosphate is 300 mg base (= 500 mg salt) orally once per week. After delivery, pregnant patients who do not have G6PD deficiency should be treated with primaquine.

[13]Persons with a positive blood smear *or* history of recent possible exposure and no other recognized pathology who have one or more of the following clinical criteria (impaired consciousness/coma, severe normocytic anemia, renal failure, pulmonary edema, acute respiratory distress syndrome, circulatory shock, disseminated intravascular coagulation, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, repeated generalized convulsions, and/or parasitemia of >5%) are considered to have manifestations of more severe disease. Severe malaria is practically always due to *P. falciparum.*

[14]Patients diagnosed with severe malaria should be treated aggressively with parenteral antimalarial therapy. Treatment with IV quinidine should be initiated as soon as possible after the diagnosis has been made. Patients with severe malaria should be given an intravenous loading dose of quinidine unless they have received more than 40 mg/kg of quinine in the preceding 48 hours or if they have received mefloquine within the preceding 12 hours. Consultation with a cardiologist and a physician with experience in treating malaria is advised when treating malaria patients with quinidine. During administration of quinidine, blood pressure monitoring (for hypotension) and cardiac monitoring (for widening of the QRS complex and/or lengthening of the QTc interval) should be done continuously and blood glucose (for hypoglycemia) should be monitored periodically. Cardiac complications, if severe, may warrant temporary discontinuation of the drug or slowing of the intravenous infusion.

[15]Consider exchange transfusion if the parasite density (i.e., parasitemia) is >10% *or* if the patient has altered mental status, non–volume overload pulmonary edema, or renal complications. The parasite density can be estimated by examining a monolayer of red blood cells (RBCs) on the thin smear under oil immersion magnification. The slide should be examined where the RBCs are more or less touching (approximately 400 RBCs per field). The parasite density can then be estimated from the percentage of infected RBCs and should be monitored every 12 hours. Exchange transfusion should be continued until the parasite density is <1% (usually requires 8-10 units). IV quinidine administration should not be delayed for an exchange transfusion and can be given concurrently throughout the exchange transfusion.

[16]Pregnant women diagnosed with severe malaria should be treated aggressively with parenteral antimalarial therapy.

Modified from http://www.cdc.gov/malaria/pdf/treatmenttable.pdf.

risk for development of retinopathy. Dose reduction may be required for patients with renal and hepatic disease.

Artemether-Lumefantrine

Artemesinin (qinghaosu) is a sesquiterpene lactone that, along with its derivatives (artemether, artesunate, arteether, and others), has antimalarial activity thought to be due to the ability to cause free radical damage in parasite membrane systems.[56] These compounds are unique in their ability to cure malaria more rapidly than other agents, with no apparent adverse events. There is no consensus on the mechanisms through which artemisinin derivatives kill malaria parasites. Lumefantrine, a dichlorobenzylidine derivative, also has an unclear mechanism of action. The fixed dose combination of artemether (20 mg) and lumefantrine (120 mg) [Coartem] is available in the United States and is FDA approved, and it is considered a first-line agent for treatment of uncomplicated falciparum malaria in countries where it is available. It is well tolerated and effective against multidrug-resistant falciparum malaria.[128] A six-dose regimen compared favorably with other agents in African children and adults with uncomplicated falciparum malaria.[105,121] Its side effect profile along with rapid parasite clearance and high cure rate for uncomplicated falciparum malaria in African infants and children make this regimen favorable.[38] Bioavailability of lumefantrine is enhanced when taken with food.[37]

Artemether-lumefantrine is not approved for use in treatment of infection with *P. vivax*, *P. ovale*, or *P. malariae* because there are few data on its efficacy for infection with these species. There may be a role for the use of artemether-lumefantrine in treating chloroquine-resistant vivax malaria, because this drug combination produces rapid clearance of the blood stage. The short half-life of lumefantrine may, however, allow for a shorter time to relapse by dormant hypnozoites.[6,169]

Atovaquone-Proguanil

A fixed-dose combination (available in adult and pediatric formulations) of atovaquone and proguanil hydrochloride is available for treatment of malaria caused by *P. falciparum* for individuals who were not taking this agent for prophylaxis. The combination is significantly more effective than either drug alone, and is effective for treatment of malaria strains resistant to other antimalarial drugs. It has fewer reported adverse events than quinine-based regimens. The combination also is likely to be active against the blood stages of *P. vivax*, *P. ovale*, and *P. malariae*, but the regimen does not have activity against the hypnozoites of *P. vivax*. Atovaquone-proguanil is significantly more effective than mefloquine, chloroquine, amodiaquine, or pyrimethamine-sulfadoxine in locations where parasites are resistant to these drugs.[81]

Mefloquine

The development of mefloquine was a major advance in the treatment of chloroquine-resistant malaria, although resistance has developed rapidly in some parts of the world where it is used widely. Mefloquine is a 4-quinolone-carbinolamine whose exact mechanism of action is unknown. Its main target is early trophozoites. Similar to chloroquine, it is not active against exoerythrocytic phases. Mefloquine has been associated with neurologic and psychiatric side effects when used for treatment or prophylaxis.[150] Vomiting occurs commonly when mefloquine is given to children younger than 5 years old and may decrease its efficacy.[145] Mefloquine should not be administered concurrently with quinine, quinidine, or halofantrine because of concern about arrhythmias. Pregnancy is not a contraindication to treatment in any trimester, although with the development of other well-tolerated medications, mefloquine is no longer the first choice for treatment of malaria in pregnancy.

Quinine and Quinidine

Quinine has been used for the treatment of malaria for centuries.[150] It is active against the mature asexual erythrocytic forms of all four species of human malaria and against the gametes of all species except *P. falciparum*, where it has activity against only immature gametes. It is not effective against exoerythrocytic forms. It may be given orally, but intravenous and intramuscular forms are available. Quinine crosses the placenta easily and may be used in the treatment of pregnant women, although close monitoring for hypoglycemia is warranted.[82]

Adverse reactions to quinine include tinnitus, headache, nausea, visual and hearing disturbances, and tremors, a constellation of symptoms called *cinchonism*. Symptoms may appear during the first 1 to 3 days of therapy and stop when treatment is terminated. Hypoglycemia may occur, particularly when the drug is used to treat pregnant women. Severe adverse events are rare but may occur idiosyncratically. Blackwater fever (hemoglobinuria) seems to occur after treatment with quinine, but the causal mechanism is unknown.

Recrudescence rates may be high when quinine is used alone because of the presence of quinine-resistant strains of *P. falciparum*. A second drug is added to treat the remaining forms. Drugs that may be used with quinine include doxycycline, tetracycline, and clindamycin.

Quinidine is a related drug that may be given intravenously; in some developed countries where intravenous quinine is unavailable, it is a treatment option for severe malaria. The mechanisms of action and adverse events are similar, although cardiac arrhythmias occur more commonly with quinidine and cardiac monitoring is advised.[159]

Primaquine

Primaquine, an 8-aminoquinoline derivative that is effective against exoerythrocytic hypnozoites, is used primarily to prevent relapses of infections with *P. vivax* and *P. ovale*, although it may not be completely effective against some strains of *P. vivax*. Despite adequate treatment with primaquine, relapses of infections with *P. vivax* and *P. ovale* do occur[11]; in some instances this may be due to inadequate dosing. It is not an effective blood schizonticide but is an active gametocidal and sporontocidal drug

for the four main species of *Plasmodium* that cause human malaria. Primaquine can cause intravascular hemolysis in individuals with G6PD deficiency. Patients should be tested for G6PD deficiency and confirmed to have normal G6PD status before being treated with primaquine. Other adverse events include gastrointestinal symptoms such as nausea, epigastric pain, anorexia, and abdominal cramps. Other rare side effects include methemoglobinemia, hemoglobinuria, and bone marrow suppression. Safety in pregnancy has not been established, and the drug should not be used by pregnant women. After delivery, women with *P. vivax* or *P. ovale* infections and without G6PD deficiency may be treated with primaquine.

Tetracycline and Doxycycline

Tetracycline, doxycycline, and the related drug minocycline have very slow activity against malarial schizonts.[150] Doxycycline and minocycline may be given once daily. They are active against chloroquine-resistant and pyrimethamine-sulfadoxine–resistant *P. falciparum*. Resistance to tetracycline has not been shown. Because of their slow activity, these agents should be given in combination with a rapidly acting drug such as quinine. These drugs should not be used in children younger than 8 years old or by pregnant or nursing women.

Antimalarial Agents Not Currently Available or Recommended for Treatment of Malaria in the United States

Other Artemisinin Derivatives

Aside from artemether-lumefantrine, the only artemisinin derivative available in the United States is parenteral artesunate, which is available on an emergency basis only from the CDC. Other artemisinin derivatives are available in other parts of the world. When used alone, recrudescence rates are high, and the drug class seems to have limited potential for prophylaxis. Oral preparations, suppositories, and oil-based preparations for intramuscular injection are available, although standardization of preparations is lacking.[128] Combinations including artemisinins are the preferred antimalarial agents worldwide[166] and have shown major utility in areas of multidrug-resistant *P. falciparum*.[1,55] In clinical trials in the Gambia, artemether was as effective as quinine and chloroquine for treatment of cerebral malaria in children.[156,162] When used in sequence with mefloquine, the combination was effective and tolerated well by patients with acute, uncomplicated falciparum malaria in Thailand, an area with multidrug resistance.[83] Later studies showed that the use of this combination may have helped halt the progressions of mefloquine resistance in the region.[112] The use of artemisinin-based combination therapies has contributed to significant reductions in malaria burden in many parts of the world. There is, however, reduced susceptibility of *P. falciparum* to artemisinin derivatives in the Cambodia-Thailand border region, likely owing to use of the artemisinins as single-drug therapy as opposed to combination therapy, leading to a WHO-led program to contain artemisinin resistance in this region.[35]

Pyrimethamine-Sulfadoxine

The combination pyrimethamine-sulfadoxine, a sulfonamide plus a dihydrofolate reductase inhibitor, exhibits synergy in its action against malaria parasites; the combination is active even against strains resistant to the individual drug components. Although pyrimethamine-sulfadoxine has been used for presumptive treatment of malaria in travelers who are taking other drugs for prophylaxis in areas where chloroquine resistance occurs, widespread resistance to the drug combination and its slow action should limit its use in nonimmune individuals with falciparum malaria. The CDC no longer recommends pyrimethamine-sulfadoxine for treatment of malaria. Although safety has not been established in pregnancy, the drug has been used widely and effectively for intermittent presumptive treatment of pregnant women in endemic areas to decrease the risk for severe anemia and placental malaria.[87,142,144]

Amodiaquine

Amodiaquine, similar to chloroquine, is a 4-aminoquinolone. It has similar efficacy but may have increased activity compared with chloroquine for the treatment of strains of *P. falciparum* resistant to chloroquine.[115] It is available in an oral preparation and is more palatable. Significant adverse events, including agranulocytosis, hepatotoxicity, and death, when used as a prophylactic agent have limited its use as a first-line agent. It is not licensed or marketed in the United States.

Halofantrine

Halofantrine is a 9-phenanthrene-methanol that has been used to treat malaria caused by chloroquine-resistant *P. falciparum*. Its major side effect is dose-related prolongation of the QT interval, and it has been associated with cardiac arrhythmias and sudden death, especially in individuals taking mefloquine prophylaxis.[16,110] Its major use was in uncomplicated malaria in areas of multidrug resistance, but cardiac toxicity at the doses required to be effective may limit its widespread use.[151] It is contraindicated in pregnant and lactating women because of embryotoxic effects. Resistance to halofantrine has limited its use in some areas. Travelers who are taking mefloquine for prophylaxis should be cautioned against accepting treatment with halofantrine if they are diagnosed with malaria during their travels. Halofantrine is unavailable in the United States.

Supportive Therapy

Malaria is a potentially fatal illness even in patients who may have developed partial immunity. Patients, especially children and those without prior immunity, with falciparum malaria should have immediate treatment and generally should be admitted to the hospital, especially in nonendemic countries such as the United States.

Patients with severe malaria should be managed in intensive care units, and experts in treatment of malaria and its complications should be consulted. Blood smears should be examined at least every 12 hours (every 4 to 6 hours for severe malaria) until parasitemia is less than 1 percent. Most patients can be treated with oral medication, although patients should be switched promptly to parenteral medication if oral medication is not tolerated. CDC* and WHO† guidelines for treatment of malaria, including management of severe malaria, are available.

Goals of supportive therapy are to maintain oxygenation and treat acidosis and hypoglycemia. Treatment with glucose infusion, oxygen, and blood transfusion may be necessary. Mechanical ventilation with positive-pressure ventilation may be needed to manage acidosis and acute respiratory distress syndrome. In some cases, hemodialysis may be needed. A high index of suspicion should be maintained for other concomitant or nosocomial infections, such as meningitis or septicemia.

Investigational Drugs and Adjunctive Therapy

Targets for new antimalarial drugs include malaria proteases and protein kinases, which play a crucial role in malaria pathogenesis.[34,132] These drugs are largely in the development phase.

Adjunctive therapies that have been shown to be beneficial include antipyretic and anticonvulsant drugs. Exchange transfusion remains a controversial option[75,159] largely owing to the lack of sufficient randomized controlled trials. Exchange transfusion may decrease parasite clearance times compared with quinine alone,[154] but there is a lack of clear survival benefit with this adjunctive therapy.[129] Adjunctive therapies that would modify or prevent the deleterious effects of inflammatory mediators, oxidative stress, iron overload, acidosis, and hypercoagulability in severe and cerebral malaria have been proposed, but limited clinical studies have not shown significant benefit.[68] A randomized study of inhaled nitric oxide in severe malaria is ongoing.[52] Some therapies, such as high-dose corticosteroids for cerebral malaria or heparin, have been shown to be harmful.[159,168] The search for effective adjunctive therapy for severe and complicated malaria continues.

PREVENTION

Prevention of malaria can be accomplished by reducing the mosquito population, using personal protection methods to prevent mosquito bites, and initiating chemoprophylaxis. Reduction of mosquito vectors is most successful when locally controlled programs are developed and maintained.[74] Strategies that combine personal protective measures with community-based control measures, such as distribution of insecticide-treated mosquito nets and indoor residual spraying, are most likely to be successful.[167] Most programs in endemic areas require a combination of preventive strategies and effective treatment modalities. Many nonendemic countries have developed recommendations for prevention of malaria in travelers.

Personal Protective Measures

A significant reduction in the incidence of malaria in children in communities where bed nets, especially when impregnated with insecticide, are used consistently has been reported from many countries.[31,45,146] In northern Ghana, community-wide use of bed nets was associated with a reduction in all-cause child mortality in young children.[10] Use of bed nets, especially those impregnated with insecticide, is recommended for travelers to malarial areas. Other personal protective measures include using mosquito repellents and insecticide-impregnated clothing or gear; wearing clothing that covers areas likely to be bitten; and remaining, if possible, in air-conditioned or well-screened areas during times when mosquitoes are biting. DEET-containing repellents are recommended most commonly for prevention of mosquito bites and are highly effective.[41] Other agents, such as picaridin, oil of lemon eucalyptus, and IR3535 are available. Picaridin is available in a 20 percent formulation, which may be used as an alternative to DEET.[98] Other agents have not been studied extensively against *Anopheles* mosquitoes.

Chemoprophylaxis

Country-specific information regarding recommendations for the use of antimalarial drugs may differ, and readers are urged to seek recommendations from national or local authorities. In the United States, these recommendations are available widely in publications from the CDC[19*] or national health information sources. Many excellent sources of health information for travelers include discussions of malaria prevention.† The Infectious Diseases Society of America has published detailed pre-travel guidelines that include recommendations for malaria prevention.[57] A list of drugs available for malaria prevention is presented in Table 219-4. Prevention of malaria for travelers is best discussed in the context of providing complete pre-travel services, advice, and information.

Antimalarial Agents Available in the United States for Prevention of Malaria

Chloroquine

A major determinant of appropriate chemoprophylaxis is whether a child is to travel to an area of chloroquine resistance. In areas of the world that have no resistance to chloroquine, the drug of choice for prevention of malaria is chloroquine. This drug is tolerated well and may be given to children of all ages, including infants.

TABLE 219-4 **Drug Regimens Used for Prevention of Malaria**

Drug	Adult Dosage	Pediatric Dosage	Comments
Chloroquine-Sensitive Areas			
Chloroquine phosphate (drug of choice)	500 mg salt (300 mg base) orally once/wk	8.3 mg/kg salt (5 mg/kg base) once/wk, up to adult dose of 300 mg base	Begin 1-2 wk before exposure, continue during exposure, and continue for 4 wk after exposure May be used in pregnant women
Hydroxychloroquine sulfate	400 mg salt (310 mg base) orally once/wk	6.5 mg/kg salt (5 mg/kg base) orally once/wk	Begin 1-2 wk before exposure, continue during exposure, and continue for 4 wk after exposure An alternative to chloroquine for use only in areas with chloroquine-sensitive malaria
Chloroquine-Resistant Areas			
Mefloquine	250 mg salt (228 mg base) orally once/wk	≤9 kg: 5 mg/kg salt (4.6 mg/kg base) orally once/wk 10-19 kg: ¼ tablet orally once/wk 20-30 kg: ½ tablet orally once/wk 31-45 kg: ¾ tablet orally once/wk >45 kg: 1 tablet orally once/wk	Begin 1-2 wk before exposure, continue during exposure, and continue for 4 wk after exposure See text for contraindications
or			
Doxycycline	100 mg daily	2.2 mg/kg/day up to 100 mg/day	Begin 1-2 days before exposure, continue during exposure, and for 4 wk after exposure; not to be used in children >8 yr old or pregnant women
or			
Atovaquone-proguanil	250 mg/100 mg (1 tablet) daily	5-8 kg: ½ pediatric tablet daily 9-10 kg: ¾ pediatric tablet daily 11-20 kg: 1 pediatric tablet daily 21-30 kg: 2 pediatric tablets daily 31-40 kg: 3 pediatric tablets daily >40 kg: 1 adult tablet daily	Begin 1-2 days before exposure, continue during exposure, and continue for 7 days after exposure Pediatric tablets contain 62.5 mg atovaquone and 25 mg proguanil hydrochloride See text for contraindications
Alternative			
Primaquine	52.6 mg salt (30 mg base) orally daily	0.8 mg/kg salt (0.5 mg/kg base) up to adult dose orally daily	Begin 1-2 days before exposure, continue during exposure, and continue for 7 days after exposure Contraindicated in people with G6PD deficiency, in pregnancy, and during lactation Prophylaxis to areas principally with *P. vivax*

Dosing of chloroquine in children is based on the child's weight and can be found in Table 219-3. In the United States, chloroquine is available only in tablets that have a very bitter taste, although some compounding pharmacies may be willing to make liquid preparations. Pharmacies can also prepare appropriate doses in capsules, and the contents of the capsule can be mixed with a small amount of liquid or semisolid food for administration. Although liquid preparations are widely available overseas and are stable for long periods,[101] many U.S. pharmacies are reluctant to prepare them. If patients are considering purchasing liquid preparations overseas, the family should be given information with the child's medication dose calculated as the base and the salt because concentrations of liquid preparations may vary. Families also should be cautioned about the greater incidence of ineffective or counterfeit medications available in some areas.

Adverse events caused by chloroquine are uncommon when the medication is used at doses needed for malaria prophylaxis. Minor side effects include gastrointestinal upset, headache, dizziness, blurred vision, and pruritus. Adverse events rarely require discontinuation of medication. Chloroquine may be taken during pregnancy and is not contraindicated in children with G6PD deficiency.

The choice of antimalarial agents in locations where drug-resistant parasites have been identified is more challenging. Chloroquine-containing regimens are not recommended for travel to areas with known chloroquine-resistant *P. falciparum*, and deaths from malaria have occurred when these regimens have been used.[17] The choice of regimen depends on the type of drug resistance, length of stay, age of the traveler, and individual medical history. Drugs currently available in the United States include mefloquine, doxycycline, atovaquone-proguanil, and primaquine.

Atovaquone-Proguanil

Atovaquone-proguanil is becoming one of the most popular choices for malaria chemoprophylaxis because of the favorable profile of side effects and the need to take the medication once daily for only 1 to 2 days before and 7 days after leaving the area of risk for malaria. Once-weekly dosing of atovaquone-proguanil for prophylaxis may be possible, but larger field trials are needed before this can be recommended.[32] The drug is effective against most *P. falciparum*, including resistant strains. It is available in adult and pediatric dosing forms and is administered daily. Adverse events most commonly reported with atovaquone-proguanil are abdominal pain, nausea, vomiting, and headache. It is not recommended at this time for prophylaxis of infants weighing less than 5 kg, for mothers nursing such infants, or for pregnant women.

Mefloquine

Mefloquine generally is well tolerated in children and can be given to infants. Dosing is based on weight, and no liquid preparation is available. Doses for older children can be supplied by breaking tablets; when small fractions of tablets are needed, pharmacists can provide individual doses in capsules. The medication has a pasty consistency but does not taste bitter. Infants tend to swallow doses better when given liquids or semisolid foods after the medication. Adverse events with mefloquine are self-limited in most cases and include gastrointestinal disturbance, insomnia, and dizziness.[79] Withdrawal rates in adults, presumably caused by the incidence of these adverse events, may impair the efficacy of mefloquine.[29] Rarely, serious adverse events, such as psychosis or seizures, have occurred after prophylactic doses of mefloquine. Consequently, mefloquine should not be used in individuals who have seizures or neuropsychiatric disorders or in individuals who have had previous adverse events with mefloquine. Mefloquine also is contraindicated in patients with cardiac conduction abnormalities, although it may be used in individuals concurrently taking β blockers for indications other than arrhythmias.

Mefloquine must be taken weekly, beginning 1 to 2 weeks before travel (with some experts recommending initiation up to 4 weeks before travel) and continued for 4 weeks after leaving the malarial area. Families may be counseled to choose a day of the week to take the medicine and to take their first dose or doses on that day of the week 1 to 2 weeks before departure. Mefloquine may be used by pregnant women in the second and third trimester and also in the first trimester if traveling to a chloroquine-resistant area.[111,155]

Doxycycline

Doxycycline is an effective antimalarial drug in parts of the world where chloroquine resistance is present. It also has been shown to be effective in areas where mefloquine-resistant *P. falciparum* exists, such as portions of Cambodia, Myanmar (Burma), Vietnam, and Thailand. Limitations in the use of this drug include that it is contraindicated in children younger than 8 years, need for daily dosing, and photosensitivity. In women, daily use of doxycycline may be associated with an increased risk for *Candida* vulvovaginitis. Gastrointestinal side effects, including nausea and vomiting, can be limited by taking the medication with meals and by avoiding bedtime dosing. Doxycycline must not be used by pregnant or lactating women. Prophylaxis with doxycycline needs to begin 1 to 2 days before travel and should be continued daily for 4 weeks after leaving the malarial area.

Primaquine

Primaquine is used most often to eradicate exoerythrocytic stages of *P. vivax* and *P. ovale*. The CDC recommends primaquine for use primarily in regions with predominantly vivax malaria. Individuals must be tested and shown not to be deficient in G6PD before they take this drug. Efficacy of primaquine compared favorably with that of mefloquine, doxycycline, and chloroquine plus proguanil in children in the holoendemic area of western Kenya.[43,139,158] It cannot be used in pregnant women.

Antimalarial Agents Not Available or Recommended in the United States for Prevention of Malaria

Tafenoquine

Tafenoquine is an investigational long-acting primaquine analog that kills parasites in the liver and in blood. It is thought to be more effective and less toxic than primaquine, but it cannot be used by individuals with G6PD deficiency or by pregnant women. No dosing regimen has been established, and it is not licensed for use,[50,140,157] but it may be available in the future.[59,71,140]

Proguanil

Proguanil has been used in combination with chloroquine to prevent chloroquine-resistant *P. falciparum*, but is less effective than mefloquine, and is not recommended or available as a single agent in the United States.

Pyrimethamine-Sulfadoxine

Pyrimethamine-sulfadoxine has been used for prevention of malaria in areas of chloroquine-resistant *P. falciparum*. An unacceptably high incidence of Stevens-Johnson reactions (fatalities in 1 in 11,000 to 25,000 users) resulted in withdrawal of the indication for using this drug for malaria prophylaxis.

Stand-By Emergency Self-Treatment

Stand-by emergency treatment (SBET) is the self-administration of antimalarial drugs when malaria is expected and prompt medical attention is unavailable within 24 hours of the onset of symptoms. This strategy is intended for emergency use only and is considered when the risks of toxicity from chemoprophylactic drugs

outweigh the benefit of avoided infection. SBET should not be recommended for travelers to high-risk *P. falciparum*-endemic areas, where chemoprophylaxis is the preferred strategy. SBET is an option for clearly defined situations, and its use must be weighed carefully with the traveler's ability to use SBET as directed.[4,137]

Vaccine

Vaccination against malaria has been a subject of active research for several decades, but a licensed vaccine is not yet available. Development of a vaccine is challenging because of the complexity of the parasite life cycle, heterogeneity of the host immune response, lack of animal models, and absence of surrogate markers of protection. Testing of vaccines is difficult because vaccine efficacy depends on conditions of transmission and the degree of immunity present in the population being studied.[152] Targets for development of a vaccine include the sporozoite (prevention of infection), the merozoite (prevention of disease manifestations by preventing invasion of RBCs), or the gametocyte (prevention of transmission by interfering with development of the parasite within the mosquito). Hundreds of candidate vaccine antigens have been identified by the *P. falciparum* genome project; choosing the most promising ones is challenging.[47]

The first malaria vaccines were directed against circumsporozoite antigen, an antigen present over most of the surface of the sporozoite. Development of these vaccines was based on the concept that sporozoites should be susceptible to antibody-mediated destruction in the extracellular space. Results of early studies with these vaccines were disappointing, with inadequate protection provided against sporozoite challenge, inconsistent relationships between antibody response and clinical efficacy, and numerous local side effects.[54,58] More recently, the candidate vaccines RTS,S/AS02A and RTS,S/ASOIE have shown promise in trials in Mozambique[2] and Kenya.[9] The candidate vaccine RTS,S/AS01, currently being studied in a phase 3 trial in seven African countries, has shown vaccine efficacy of 50.4 percent against malaria, with efficacy against severe malaria of 45.1 percent.[134] Merozoite surface proteins are another group of antigens that have been studied in connection with the development of a blood-stage, or asexual, malaria vaccine.[118] The SPf66 vaccine, derived from three merozoite proteins linked to a 4-amino acid from a *P. falciparum* circumsporozoite protein, has been tested in clinical trials in Colombia, Tanzania, and the Gambia.[3,30,153] Although initial studies in countries in South America with low malaria endemicity showed promise, investigations in African countries with high endemicity have been disappointing, with protective efficacy ranging from 31 percent (95% confidence interval [CI], 0% to 52%) in Tanzania to 8 percent (95% CI, 18% to 29%) for first or only clinical episodes and 3 percent (95% CI, –24% to 24%) in overall incidence of clinical episodes in the Gambia.

Vaccines that block transmission from humans to mosquitoes would reduce the reservoir of infected mosquitoes and reduce transmission on a population level. The poor immunogenicity and diversity of gametocyte antigens have proved challenging to this approach to the development of a vaccine, and no vaccines of this type have been used yet in clinical trials. Future vaccines are likely to use a combination approach that incorporates target antigens from all three stages of the parasite. To have a significant impact on decreasing worldwide burden of malaria, vaccines ultimately may need to be combined with other prevention strategies, including protection against mosquito bites with insecticides and treated bed nets and intermittent preventive treatment with antimalarial drugs.[47]

CHAPTER 220

Leishmaniasis

Lynne S. Garcia

Leishmaniasis is a parasitic disease affecting more than 12 million people in 88 countries, with 350 million more at risk and more than 400,000 new cases reported each year.[4] The infection consists of a group of diseases that may affect the skin, mucous membranes, or viscera with a wide range of clinical presentations caused by obligate intracellular hemoflagellates of the genus *Leishmania*. Infection is transmitted by several genera and species of phlebotomine sandflies. Three major clinical syndromes usually are recognized: cutaneous (CL), mucocutaneous (MCL), and visceral (VL) leishmaniasis. Macrophages of the skin, mucous membranes, or spleen, liver, and bone marrow (reticuloendothelial system) are parasitized. New species continue to be identified, particularly in the New World. However, the taxonomy of leishmaniasis is controversial, and species differentiation is currently based on molecular techniques rather than morphology and clinical presentation.[9]

Studies on the components of sandfly saliva suggest that substances may partially influence the tropism of the parasite and therefore the resulting disease. The amount of a vasodilatory peptide, maxadilan, in sandfly saliva appears to correlate with the type of human infection.[47] Sandflies in Brazil that transmit *Leishmania chagasi* VL have relatively large amounts of maxadilan in their saliva that causes marked vasodilation and may encourage visceralization of the parasites. The same complex of sandflies in Costa Rica, which have relatively small amounts of the vasodilatory peptide in their saliva, transmit organisms that produce a nonulcerating and nonvisceralizing *L. chagasi* infection that is limited to the dermis.

The clinical manifestations of leishmaniasis appear to depend on a complex set of factors, including tropism and virulence of the parasite strain, as well as the susceptibility of the host, which may be determined genetically.[32] Cell-mediated immune mechanisms appear to be the

major factors in modulating these diseases (Table 220-1). Disease syndromes range from self-healing cutaneous lesions to debilitating mucocutaneous infections, subclinical viscerotropic dissemination, and fatal visceral involvement.

In CL, *L. tropica* (with some notable exceptions), *L. major*, *L. aethiopica*, and *L. mexicana* tend to be restricted to reticuloendothelial cells of the skin, and infections generally are self-limited, with spontaneous healing. Similarly, in MCL *L. braziliensis* can invade the

TABLE 220-1 **Clinical Syndromes Caused by *Leishmania* Species and Their Geographic Distribution***

Clinical Syndromes	Leishmania Species†	Location
Visceral Leishmaniasis		
Kala-azar: Generalized involvement of the reticuloendothelial system (i.e., spleen, bone marrow, liver)	*L. (L.) donovani*	Indian subcontinent, northern and eastern China, Pakistan, Nepal
	L. (L.) infantum	Middle East, Mediterranean littoral, Balkans, Central and southwestern Asia, northern and northwestern China, northern and sub-Saharan Africa
	Canine visceral leishmaniasis	Foxhounds in 18 states (United States)
	L. (L.) donovani (archibaldi)	Sudan, Kenya, Ethiopia
	L. (L.) spp.*	Kenya, Ethiopia, Somalia
	L. (L.) chagasi	Latin America
	L. (L.) amazonensis	Brazil (Bahia State)
	L. (L.) tropica	Israel, India, and viscerotropic disease in Saudi Arabia (U. S. troops)
Post–kala-azar dermal leishmaniasis	*L. (L.) donovani*	Indian subcontinent, East Africa
Old World Cutaneous Leishmaniasis		
Single or limited number of skin lesions	*L. (L.) major*	Middle East, northwestern China, northwestern India, Pakistan, Africa
	L. (L.) tropica	Mediterranean littoral, Middle East, western Asiatic area, Indian subcontinent
	L. (L.) aethiopica	Ethiopian highlands, Kenya, Yemen
	L. (L.) infantum	Mediterranean basin
	L. (L.) donovani (archibaldi)	Sudan and East Africa
	L. (L.) spp.	Kenya, Ethiopia, Somalia
Diffuse cutaneous leishmaniasis	*L. (L.) aethiopica*	Ethiopian highlands, Kenya, Yemen
New World Cutaneous Leishmaniasis		
Single or limited number of skin lesions	*L. (L.) mexicana* (chiclero ulcer)	Central America, Mexico, Texas, Oklahoma, Arizona
	L. (L.) amazonensis	Amazon basin and neighboring areas, Bahia and other states in Brazil
	L. (V.) braziliensis	Multiple areas of Central and South America
	L. (V.) guyanensis (forest yaws)	Guyana, Suriname, northern Amazon basin
	L. (V.) peruviana (uta)	Peru (western Andes) and Argentinean highlands
	L. (V.) panamensis	Panama, Costa Rica, Colombia
	L. (V.) pifanoi	Venezuela
	L. (V.) venezuelensis	Venezuela
	L. (V.) colombiensis	Colombia and Panama
	L. (L.) chagasi	Central and South America
Diffuse cutaneous leshmaniasis	*L. (L.) amazonensis*	Amazon basin and neighboring areas, Bahia and other states in Brazil
	L. (V.) pifanoi	Venezuela
	L. (L.) mexicana	Mexico and Central America
	L. (L.) spp.	Dominican Republic
Mucosal leishmaniasis	*L. (V.) braziliensis* (espundia)	Multiple areas in Latin America

*This table contains the most common species; not every organism is listed above.

†>*(L.)* subgenus *Leishmania; (V.)* subgenus *Viannia.*

reticuloendothelial cells of the skin and the mucous membranes of the nose, mouth, and pharynx, resulting in serious disfigurement, if not death. Some strains of *L. tropica* may cause viscerotropic disease. In cases of VL (kala-azar), *L. donovani*, *L. chagasi*, and *L. infantum* invade cells of the reticuloendothelium of viscera, usually causing splenomegaly and occasionally hepatomegaly and pancytopenia; untreated, the disease is progressive and generally fatal.

Individuals with acquired immunodeficiency syndrome (AIDS) may have atypical manifestations. Dermotropic strains of *L. infantum* are known to cause visceral infection in immunocompromised patients with AIDS.[45] VL is quite prevalent among AIDS patients in certain geographic areas (southern Spain), with a high proportion of cases being subclinical. Like other opportunistic infections, subclinical VL can be found at any stage of human immunodeficiency virus (HIV)-1 infection, but symptomatic cases appear mainly when severe immunosuppression is present.[5] HIV-*Leishmania* coinfection is being seen increasingly frequently in the Mediterranean basin, especially in Spain, France, and Italy.

THE ORGANISM

In vertebrate hosts, *Leishmania* spp. are obligate intracellular parasites that exist only in the amastigote stage. The species that infect humans are usually morphologically indistinguishable from one another at both the light microscopic and ultrastructural levels. The organisms are round to oval bodies approximately 2 to 4 µm in diameter, with a single nucleus, a specialized mitochondrial structure that has extranuclear DNA termed a *kinetoplast*, and no free flagellum. Amastigotes are engulfed by macrophages and reside within the parasitophorous vacuole of the macrophage host. They multiply by binary fission and eventually destroy the host cell. Subsequently, they are phagocytized, and the process occurs repeatedly.[22]

When the vector, a female sandfly, feeds on an infected person, it may ingest an infected cell from blood or tissue. Amastigotes are liberated in the fly's midgut, and within a few hours, transformation to the promastigote stage occurs.[26] Promastigotes are elongated flagellates 15 to 25 µm long × 1.5 to 3.5 µm wide, each with an anterior, free flagellum that measures approximately 15 to 28 µm in length and may vary morphologically from a short and stumpy to an elongated form. Binary fission then begins, and large numbers of promastigotes are produced and gradually move forward to the pharynx, buccal cavity, and mouth parts. Depending on temperature and the species of sandfly, at 8 to 20 days, the mouth parts of the fly may be blocked partially or completely by huge numbers of promastigotes. These organisms may be dislodged into the bite wound when the female sandfly (*Phlebotomus*, *Lutzomyia*) next takes a blood meal. Promastigotes have surface molecules that bind to several macrophage receptors. The phagocytized promastigote forms transform into amastigotes within the parasitophorous vacuole, and multiplication takes place.

Amastigotes can be seen in Giemsa- or Wright-stained tissues or smears by light microscopy, with the nucleus and kinetoplast staining bright red and the cytoplasm pale blue. In Novy-McNeal-Nicolle (NNN) culture medium at 24°C (75.2°F), the organisms grow readily and assume the promastigote or insect form.

In the past, specific and subspecific taxonomy designations have been determined by the clinical syndrome caused by an isolate in a particular geographic area. Also, various molecular techniques have been used to characterize the strains and species of clinical isolates: endonuclease restriction studies of kinetoplast DNA (K-DNA), buoyant density of K-DNA and mitochondrial DNA (M-DNA) on cesium chloride, leishmanial isozyme patterns, monoclonal antibody specificity, and exoantigen secretory factor 4 serotyping.[3]

EPIDEMIOLOGY

Leishmaniasis is mainly a zoonosis, although in certain areas of the world primarily human-vector-human transmission occurs. The World Health Organization (WHO) estimates that 1.5 million cases of CL and 500,000 cases of VL occur every year.[19] With recent outbreaks in many areas of the world, including Brazil, India, Italy, Spain, Sudan, and Kenya, leishmaniasis has become more widely recognized as an important emerging infectious disease in many developed as well as underdeveloped countries.[12,27] Although the parasite usually is transmitted via the bite of the sandfly vector, it may be transmitted also as a result of a laboratory accident, direct person-to-person transmission, and blood transfusion.[34] In addition, evidence indicates that it may be transmitted either in utero or during the peripartum period.

The phlebotomine sandfly, the vector for leishmaniasis, was first identified by Bonanni in 1691.[18] The name of the genus, *Phlebotomus*, however, was coined in 1840 by Rondani and Berte. In 1907, the first description of an American phlebotomine sandfly was made by Coquillet. In 1909, Gaspar Vianna in Brazil identified the parasites responsible for cutaneous leishmaniasis later identified as *L. braziliensis* in 1911.[17] Concurrently, Lutz and Neiva identified the first three species of sandflies in Brazil. *Lutzomyia* sandflies were later named after Adolfo Lutz. To date, 229 species have been identified. It was not until 1921, however, that the Sergent brothers implicated phlebotomine sandflies in the transmission of cutaneous leishmaniasis in Algeria. The evidence was substantiated by the work of Aragao in 1922 and Pessoa and Pestana in Brazil in 1940. Later, in 1950, it was discovered that the different forms of leishmaniasis infesting the American continent were caused by distinct species of the parasite. The research on leishmaniasis and sandflies has shed light on the transmission of other zoonotic illnesses, including Trypanosomatids (Crithidia, Endotrypanum, and Trypanosoma), and several viruses including Rhabdoviridae, Bunyaviridae, and Reoviridae, all isolated from phlebotomine sandflies. Sixty nine serotypes of different arboviruses isolated from sandflies have been identified in the Amazon region.[18]

OLD WORLD CUTANEOUS LEISHMANIASIS

Definition and Epidemiology

Old World CL is caused by *L. major* (rural), *L. tropica* (urban), and *L. aethiopica*. It is found throughout the Middle East, along the Mediterranean basin and islands, and in East and West Africa, India, and southwestern Asia.[50] In humans, infection by *L. tropica* usually produces skin ulcers in which intracellular (amastigote) parasites can be found within macrophages in and around the lesions. These organisms are rarely found in spleen, liver, or bone marrow; however, several recent reports have described *L. tropica* isolates from patients with VL. In many areas, dogs or rodents are found to be naturally infected and are thought to be the natural reservoirs of infection. Various *Phlebotomus* spp. transmit the infection, although person-to-person transmission is possible and is the basis of the long-time practice in middle and central Asia of immunizing inoculation, that is, "leishmanization" to prevent possible disfigurement by a natural infection (Fig. 220-1).

Old World leishmaniasis, or Oriental sore (Delhi boil or Aleppo button), can be classified into "wet" and "dry" types. The wet, or rural, form is caused by *L. major* and is found chiefly in various rodents on the edge of deserts. The dry, or urban, type is caused by *L. tropica*, and is transmitted by phlebotomine species that frequently feed on humans and dogs. The dry, or urban, form of Oriental sore has a long incubation period, long duration of active infection, and large numbers of parasites in the dermis. The moist, or rural, type has a short incubation period, with rapid healing and few parasites in the skin. *L. aethiopica* is restricted to the mountain valleys of the Rift Valley of Ethiopia and Kenya, where rock and tree hyraxes are infected regularly. Humans become infected when they intrude in these areas. This form of CL is usually self-limited,[62] although in a small number of individuals (1/100,000), nonhealing diffuse cutaneous (DCL) disease has been reported.

FIGURE 220-1 ■ *Leishmania tropica.* Immunization by an induced lesion. (From a nonprofit cooperative endeavor by numerous colleagues under the editorship of Dr. Herman Zaiman, New York.)

Pathology

At the bite site, promastigotes are engulfed by histiocytes, in which they multiply. The histiocytes are destroyed, and amastigotes are released into tissues, where the process is repeated. Lymphocytic and plasma cell infiltration along with histiocytic hyperplasia occurs, and in some lesions, epithelioid and giant cells may be seen. Hypertrophy of the stratum corneum and hyperplasia of dermal papillae occur early, usually followed by necrosis of the area caused by capillary obstruction and endothelial proliferation; eventually the epithelium overlying the center of the lesion becomes necrotic and is sloughed, with the formation of a characteristic ulcer. Secondary neutrophil infiltration also occurs. At this point, a depressed ulcer with a raised purpuric indurated border and a base of friable granulation tissue is present. Amastigotes are located within the cells, although during the period of necrosis, organisms may be seen outside cells but division does not occur.

With *L. tropica*, development of the cutaneous lesion may take weeks to months, with large numbers of parasites present in nests of macrophages. In *L. major* infection, the onset is rapid, with an outpouring of lymphocytes and plasma cells; parasites are sometimes difficult to find. In some cases, satellite lesions form close to the primary lesion so that local spread is seen. The pathologic reaction may be florid, with marked pseudoepitheliomatous hyperplasia that can be mistaken for carcinoma. Secondary bacterial infection may complicate the lesion and delay healing. Once the ulcer heals, however, usually by fibrosis, the patient has long-lasting immunity (Fig. 220-2).

Several manifestations of CL have been described and seem to be associated with the ability of the patient to respond to the infection by cell-mediated immune mechanisms. Whether these mechanisms are directly responsible for protection in humans is still not certain. However, in a small number of patients, the inability to mount a suitable cell-mediated immune reaction is associated with specific anergy to leishmanin and an indolent nonhealing lesion.[14] This condition is known as diffuse cutaneous leishmaniasis (DCL). Characteristically, lesions in DCL are filled with large, parasite-containing histiocytes, and lymphocytes are absent. Recent studies of DCL from the Dominican Republic suggest that immune suppression plays an important role in this form of the disease.

At the other extreme is a small group of patients whose cell-mediated immune response to infection with leishmanial organisms is exaggerated and the lesions heal by scarring. At the edge of the scar, however, new lesions appear, so the disease seems to extend from the margins. Eventually, tissue damage may be rather extensive. On histologic examination, many lymphocytes, plasma cells, epithelioid cells, and large multinucleated giant cells are seen. Organisms are difficult to locate but sometimes can be cultured from these lesions. This form of CL is called

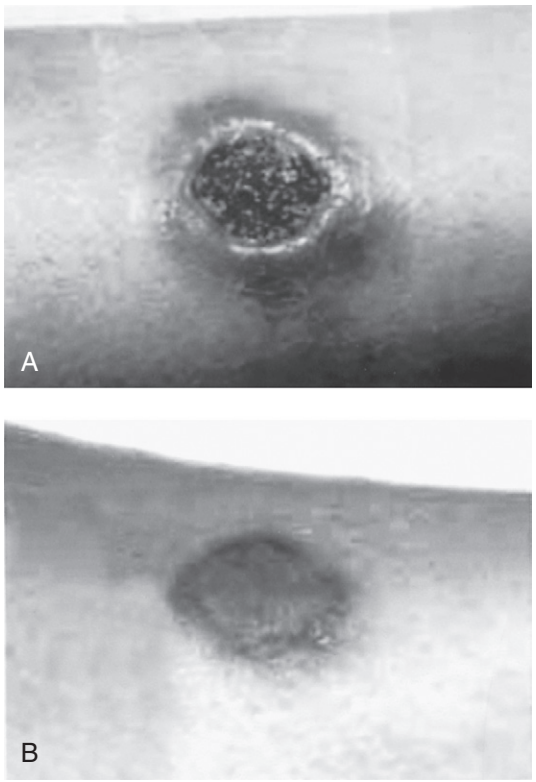

FIGURE 220-2 ■ **A,** Typical cutaneous leishmaniasis ulcer. **B,** Healed cutaneous leishmaniasis ulcer.

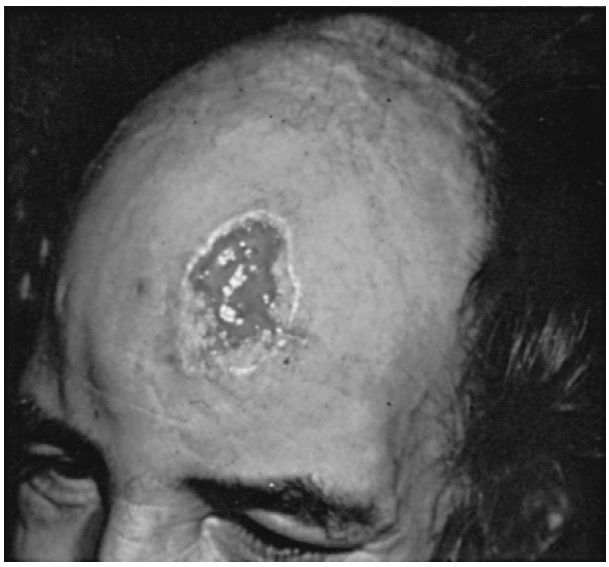

FIGURE 220-3 ■ Healing cutaneous leishmaniasis in a patient from Venezuela.

leishmaniasis recidivans. Patients exhibit marked delayed hypersensitivity to leishmanin. Studies by Turk and Bryceson[58] have provided the concept that CL may be a spectrum of diseases analogous to leprosy. They consider DCL to be at one end of the spectrum and representative of anergy and leishmaniasis recidivans to be at the other end and representative of marked delayed hypersensitivity, with an ordinary Oriental sore as the center in which balance exists.

Clinical Manifestations

The disease usually begins with the appearance of a pruritic, red, vesicular papule that appears weeks to months after the bite of a sandfly. The papule gradually enlarges, often measuring 1 to 2 cm in diameter. When the surface of the papule dries, it encrusts and drops off to reveal a shallow ulcer. The ulcer may or may not enlarge progressively and characteristically has raised, sharp, indurated, deep purpuric margins. Healing usually occurs in 3 to 18 months, with an obvious hypopigmented or hyperpigmented depressed scar frequently remaining (Fig. 220-3). However, single or multiple papules often heal directly without extensive ulceration. If the lesions do not become infected secondarily, usually no complications occur.

Diagnosis

Definitive diagnosis depends on demonstrating the amastigotes in tissue specimens or the promastigotes in culture. Microscopic examination of Giemsa-, Wright-, or other rapid blood-stained smears of tissue obtained from non-necrotic areas of the ulcer or from the base should be performed. Aspiration and culture of tissue fluid taken from the ulcer margin can be positive; however, biopsy material taken from the edge of the ulcer is preferred and should be examined histologically, as should small fragments macerated in saline and inoculated into NNN medium or Schneider insect medium supplemented with antibiotics. It is very important to make sure the lesion is cleaned thoroughly to remove all secondary infectious organisms (i.e., contaminating bacteria or fungi) before taking the punch biopsy specimen for culture. The specimen of choice would be a collection of several punch biopsy specimens taken from the most active lesion areas. Clinically, the lesions are often characteristic, so the diagnosis should be suspected in a patient who has visited an endemic area.

Although the leishmanin test is usually positive in patients with ulcerated lesions, the material is not readily available in the United States. However, a positive leishmanin skin test may help distinguish a variety of skin lesions such as syphilis, tropical phagedenic ulcer, yaws, tuberculosis, and various fungal diseases. The indirect fluorescent antibody test or direct agglutination test may be positive in this infection, although often at low titer and, therefore, of little value.

Treatment

Uncomplicated *L. tropica* lesions generally respond well to chemotherapy or conservative management. Because Old World CL usually remains a local lesion, if the ulcer is not disfiguring and appears to be healing, allowing the lesion to heal spontaneously is appropriate.[62] In most cases, systemic therapy with[28] stibogluconate sodium is effective.

Liposomal amphotericin B (AmBisome) has been used for treatment of visceral leishmaniasis, and more recently

for treatment of cutaneous leishmaniasis.[24] However, a healthy 38-year-old man treated with liposomal amphotericin B for cutaneous leishmaniasis acquired during military duties in Iraq reported memory difficulties and confusion after completion of his therapy. Extensive evaluation revealed no other source, and his cognitive issues were attributed to liposomal amphotericin B toxicity (mentioned in the package insert). The patient's symptoms resolved over a few weeks, which is consistent with published data about the drug's tissue penetration and metabolism. This is a potential side effect of liposomal amphotericin B that can be observed in otherwise healthy patients.[24]

Various imidazoles (e.g., ketoconazole, itraconazole) have been used and appear to have limited antileishmanial activity. An ointment containing paromomycin (aminosidine) and methylbenzethonium (Leshcutan) has been reported to show some promise in treating cutaneous lesions, especially in Israel.[9,53]

A 31-year-old man with DCL from 3 years of age experienced profound physical and psychosocial repercussions, and with no effective treatment available at present, was treated with miltefosine.[65] The patient was treated for 120 days, 100 mg/day for 1 week, then 150 mg/day subsequently. Lesions were free of parasites at 43 days, and no signs of infiltration were present at day 76. No adverse side effects were observed. The dramatic clinical effect of miltefosine in this patient appears to fully justify further evaluation of this experimental therapy in DCL.

Prevention

Residual spraying for sandflies, eradication of reservoir hosts, and vaccination procedures have reduced and limited this disease in many areas of the Middle East and central Asia. Because of the indolent nature of the healing with vaccination and the possibility of visceralization, this practice has been discontinued in Israel. The customary method for controlling leishmaniasis and sand fly bites in Israel involves the spraying of large quantities of residual insecticides on walls of houses and neighboring surfaces. However, the high summer temperatures, strong radiation, and dust limit the efficacy of the method.[41]

AMERICAN CUTANEOUS LEISHMANIASIS

The epidemiology and etiology of American CL are quite complex. In South and Central America, many varieties of leishmaniasis exist, including the mucocutaneous form, or espundia. In contrast to Old World CL, American cutaneous disease is tied closely to the forests of South and Central America, and each variety has its own distinct epidemiologic, pathologic, and clinical picture.[25] Whether designating each of the clinical types of American CL by a separate species of *Leishmania* is justified remains unclear. With regard to the American cutaneous forms, two main groups of organisms are distinguished: the *L. mexicana* and *L. braziliensis* complexes (Figs. 220-4 and 220-5). The former are often characterized by rapid growth in culture medium and in hamsters, and the latter are organisms that grow slowly in culture and hamsters.

FIGURE 220-4 ■ Chiclero ulcer *Leishmania (mexicana) mexicana.* A typical chronic lesion of the external ear is evident. Such lesions never metastasize.

FIGURE 220-5 ■ Mucocutaneous leishmaniasis: *Leishmania (braziliensis) braziliensis.* The entire nasal septum has been eroded. Few organisms could be found by smear or biopsy; however, promastigote forms were cultured from the lesion.

Leishmania Mexicana Complex

L. (mexicana) mexicana is transmitted by species of sandflies of the genus *Lutzomyia* (Fig. 220-6). Many rodent reservoir hosts exist. This species is found in Mexico, Guatemala, and Belize. It causes mild infection, often a single cutaneous lesion that is self-limited, or persistent chronic ear lesions, as well as chiclero ulcer.[2] One case of disseminated disease has been reported. This species is probably responsible for the occasional cases of CL found in the southern portion of the United States. The range of endemic infection has now been expanded within the United States to include areas within Arizona that are farther north than the southern Texas site previously

FIGURE 220-6 ■ Sandfly.

identified.[51] Apparently, wood rats serve as the primary wild reservoir hosts in these two states.

CL is endemic in south-central Texas and appears to be spreading northward into the Dallas–Ft. Worth metropolitan area, affecting humans, cats, and dogs. Multiple vectors and rodent reservoir hosts exist within Texas; vector-borne sand fly–based transmission is probably the primary means of disease spread in this area. Because of poor surveillance and infrequent diagnosis in the United States, whether leishmaniasis may have been present within at-risk canine and feline populations before the more recently recognized "outbreaks" in foxhounds and humans is not known. Evidence suggests that this disease may continue to emerge as a result of changes in the environment and closer contact between pets and sylvatic ecosystems.[43,63]

L. (mexicana) amazonensis is found along the Amazon basin and in Trinidad. It rarely infects humans but is transmitted by various species of *Lutzomyia* in rodents. In humans, it causes a mild, self-limited skin lesion. Occasionally, disseminated disease reportedly develops.

Leishmania Braziliensis Complex

L. (braziliensis) braziliensis or *L. (Viannia) braziliensis* is transmitted by various species of *Lutzomyia* in Brazil and the forest areas east of the Andes. It was originally described by Gaspar Vianna in Brazil as the cause of Bauru's ulcer.[17] This organism is the "prototype" of American CL or MCL, or espundia. It may cause destructive ulcerative lesions of the naso-oropharynx as a result of early or late metastases from a more superficial site.

L. (braziliensis) guyanensis is transmitted by species of *Lutzomyia* in Guyana, Suriname, Brazil, and Venezuela. It causes single or multiple spreading cutaneous ulcers over many parts of the body and is believed to metastasize along the lymphatics but does not visceralize. The organism sometimes spreads to the naso-oropharynx and causes mucosal disease. It sometimes is referred to as pian bois and forest yaws.

L. (braziliensis) panamensis is transmitted by species of *Lutzomyia* in Panama and possibly farther north and south. It may cause single to several superficial ulcers and may metastasize along the lymphatics to the naso-oropharynx. A cluster of five cases was reported of CL with *L. (Viannia) panamensis* among men attempting emigration from East Africa, who acquired the infection while traveling from Central America to the United States. Identification of the infecting species revealed important information related to a well-defined human smuggling route with potential public health consequences from this emerging infectious disease risk.[10]

L. (braziliensis) peruviana is seen in Peru on the western slopes of the Andes to an altitude of 3000 m. It causes a single or a few self-healing ulcers. No oronasopharyngeal spread occurs. Often, it is referred to as *uta*. Dogs are regarded as the reservoir hosts.

In MCL as represented by espundia, researchers estimate that nasal involvement may occur in as many as 80 percent of infections, up to 30 percent of which eventually mutilate the mucous membranes of the mouth, nose, palate, larynx, and trachea. These cases are often fatal because of the intervening sepsis. Lesions of the mucous membranes often occur years to decades after a cutaneous ulcer has healed. Once mucous membrane involvement occurs, the infection may be difficult to cure using chemotherapy.

Diagnosis

The discussion of Old World CL includes the various methods for diagnosis. In mucocutaneous disease, the fluorescent antibody test using amastigote antigen is most useful in that it is positive in 75 to 85 percent of cases, with declining titers after therapeutic cure.[61] A direct agglutination test using promastigotes also is used frequently, as is enzyme-linked immunosorbent assay (ELISA).[61] A DNA–DNA hybridization or dot-blot test that is highly sensitive and species-specific in tissue or biopsy specimens has been used.[37] Isozyme analysis of isolated organisms currently is being used to help identify the species causing the infection.

Treatment

As in Old World CL, treatment of most lesions is effective using pentavalent antimonials. Because prompt and adequate therapy for primary cutaneous lesions may reduce the risk for subsequent metastatic disease in potentially mucocutaneous infections, pentavalent antimony should be used. If lesions should prove unresponsive to antimony therapy, amphotericin B should be tried. Liposomal amphotericin treatment has been useful in selected studies.[15] Relapses with this form of leishmaniasis are common and must be retreated. Pentavalent antimonials are moderately effective in treating mild mucosal disease but are often unsatisfactory with severe mucosal involvement. Diffuse cutaneous leishmaniasis, a disseminated form of the disease, should be treated with stibogluconate sodium[28]; when relapses occur, amphotericin B should be used next because this disease is usually refractory to further antimony therapy.[15,48] Pentamidine also has been used with limited success when lesions have proved resistant to antimony compounds. Pentavalent

antimony–resistant cutaneous disease, such as leishmania recidivans, has been treated with limited success with ketoconazole 400 to 600 mg daily for 4 weeks. Miltefosine, an oral antileishmanial agent effective against VL, has shown promise for the treatment of American CL (*L. panamensis* and *amazonensis*).[15,55]

Prevention

This disease is extremely difficult to prevent because it is a forest disease. It can be avoided only by sleeping in tents under fine-mesh netting, wearing long-sleeved clothing, and using insect repellents. The presence of *Leishmania* parasites in the unaffected skin and peripheral-blood monocytes of a high proportion of patients even after treatment and the acquisition of infection by sand flies support the plausibility of anthroponotic transmission of American CL.[60] As travel to Latin America has become increasingly common, cutaneous leishmaniasis is increasingly seen among returning travelers; for instance, the number of observed cases has doubled in the Netherlands and tripled in the United Kingdom in the past decade.[52] A high proportion of cases are acquired in rural or jungle areas of the Amazon basin. In children acquiring *L. (Viannia) braziliensis* infections, the major risk factor for acquisition of disease was the presence of an adult in the household with CL within the last year.[1] Humans may serve as both reservoir and source of infection for young children. Vaccine development against American CL is underway.[30,44,49]

VISCERAL LEISHMANIASIS

VL is caused by various organisms in the *L. donovani* spp. complex in Asia and Africa, as well as by *L. infantum* in southern Europe and North Africa and the related *L. chagasi* in Brazil and elsewhere in the New World. Strains of *L. tropica* from the Middle East and *L. amazonensis* from Latin America also have been found to cause this syndrome.

VL, or kala-azar, is found in a broad belt that extends from the Strait of Gibraltar across the Mediterranean through Asia to the east coast of China, at latitude between 30 and 48 degrees north. It is transmitted by various species of sandfly, although congenital and blood-borne infections also can occur.[64] VL has been reported from 47 countries, but the Sudan and India account for more than half the cases. In the Western Hemisphere, it is found in Brazil, northern Argentina, Paraguay, Venezuela, Colombia, Guatemala, and Mexico. Kala-azar appears to exist in at least three epidemiologic forms.

The Mediterranean type of VL, with a canine reservoir, infects young children (1 to 4 years of age); dogs, foxes, and feral animals are the reservoirs *(L. infantum)*. This type extends from the Mediterranean littoral through central Asia into China; it is also present in parts of South America *(L. chagasi)*, where foxes and dogs are reservoir hosts. In Brazil, young males most often are infected. Infected dogs are the primary reservoir for zoonotic visceral leishmaniasis in endemic regions and the most significant risk factor predisposing humans to infection.[43] Dogs have a wide range of clinical presentation with infection with *L. infantum*, ranging from asymptomatic to fatal visceral disease.

An Indian type *(L. donovani)* of VL with a human reservoir predominates in Indian children between 5 and 15 years of age; humans are the only known reservoir. Although sought, evidence of natural infection in dogs has not been found. No evidence of rodent reservoirs exists.

The African type of VL uses rodents as the reservoir hosts. The Nile rat in the Sudan and probably the gerbil in Kenya are the reservoirs. In Kenya, researchers have noted that kala-azar often is related to old or eroded termite mounds where young males often congregate (see Fig. 220-5).

Pathology

The main pathologic lesions are the result of reticuloendothelial cell hyperplasia, especially in the spleen and liver (Fig. 220-7). Later, the bone marrow and lymph nodes are filled with infected macrophages, and a concomitant leukopenia and anemia develop (i.e., pancytopenia). Also, the kidneys may be filled with infected macrophages, and invasion of the submucosa and mucosa of the duodenum and jejunum results in hypertrophic congested and edematous villi. Small ulcerations and

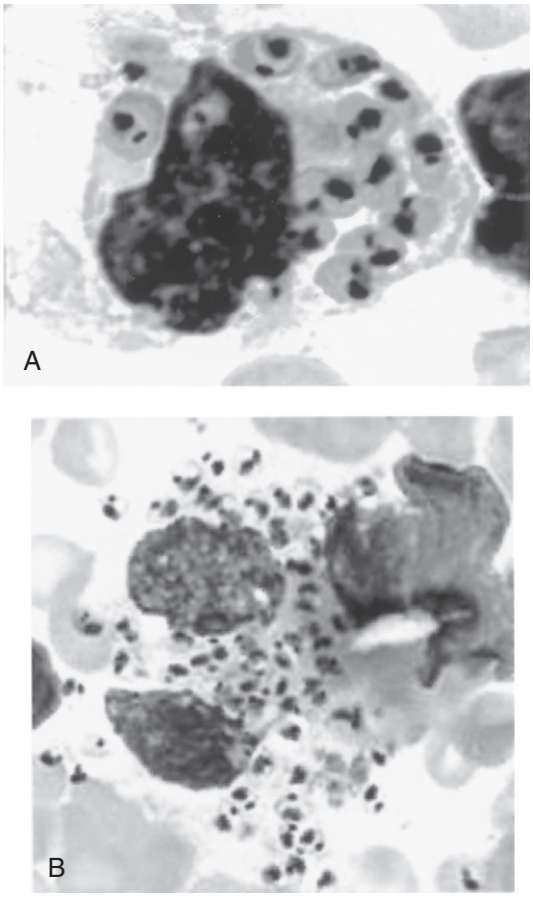

FIGURE 220-7 ■ **A,** *Leishmania tropica* in a macrophage. **B,** *Leishmania donovani* in a liver touch preparation.

hemorrhages may occur. The spleen gradually enlarges, sometimes assuming enormous proportions, and eventually extends into the pelvis. Splenic infarcts are a frequent development. The capsule is thickened, and, more deeply, the sinuses are dilated. Erythrophagocytosis by histiocytes is seen commonly, and the anemia so typical of kala-azar may in part be the result of such sequestration of red cells. Kupffer cells of the liver, filled with amastigotes, are swollen and hyperplastic, and centrilobular necrosis or fatty infiltration of the hepatic parenchyma often is observed. In late-stage or chronic disease, increased hepatic fibrosis may give a nodular cirrhotic appearance. Lymphadenopathy, especially of the mesenteric glands, is an early finding, and large numbers of parasite-filled macrophages are present. The bone marrow often is filled with parasitized histiocytes that replace the normal marrow elements; such replacement results in myelophthisic anemia.

The immunologic response to kala-azar infection is imperfectly understood. At the bite site, a small, pea-sized, dermal lesion may form (i.e., a leishmanioma); the parasites, initially localized in dermal macrophages, disseminate within the macrophages to the spleen, liver, bone marrow, and lymph nodes.

The infection outcome depends on the host's ability to raise a suitable cell-mediated immune response and the virulence of the invading organism. Experimentally, resistance in mice appears to be determined by a single autosomal gene. Researchers have shown in experimental infections that the disease is controlled by the T_H1 subset of $CD4^+$ and $CD8^+$ T cells; these cells are related to the production of cytokines such as interferon (IFN)-γ, interleukin-2, and tumor necrosis factor–α.[36] Infection with *L. donovani* amastigotes induces a Th1 cytokine milieu in both dendritic cells and T cells.[23] Cytokines activate macrophages to kill intracellular amastigotes by oxidative and nonoxidative mechanisms. Studies in mice indicate that nitric oxide is an important factor in killing amastigotes. If the infection is not eliminated or controlled by the host's cellular immune response, it then becomes clinically evident. Lymphocytogenesis and histiocytogenesis occur in affected organs, with resultant hepatosplenomegaly and lymphadenopathy. Polyclonal B-cell activation ensues and causes hyperglobulinemia. This outpouring of humoral antibodies, chiefly IgG and largely nonspecific, is not protective and may represent more than half the total serum proteins of the patient. The specific antibodies produced during active disease have diagnostic significance. Fluorescent antibody, ELISA, indirect hemagglutination, and complement-fixation tests are reasonably reliable diagnostic procedures.

Resistance to kala-azar is essentially absent once the infection has become evident clinically. However, after chemotherapeutic cure, acquired immunity emerges; delayed hypersensitivity, as demonstrated by the Montenegro (leishmanin) skin test (see later), also becomes apparent. Moreover, the hypergammaglobulinemia abates concomitant with chemical cure and the appearance of delayed hypersensitivity. Usually, immunity to VL is complete and long-lasting after chemotherapeutic cure. However, relapse, as seen in post–kala-azar dermal leishmaniasis, is characterized by delayed hypersensitivity, dermal localization of parasites, and moderate hypergammaglobulinemia. Although macrophage activation results in enhanced phagocytosis of parasites, macrophages remain unable to eliminate parasites. The appearance of dermal delayed hypersensitivity at the time that acquired immunity appears suggests that cell-mediated immunity plays an important role in protection. Further work on this aspect of VL is needed. The genetics of resistance in humans remains unclear.

Clinical Manifestations

The incubation period varies widely from 6 weeks to 6 months but has been reported to be as short as 10 to 14 days and as long as 10 years. A primary skin nodule is rarely seen, although in African leishmaniasis it is a more regular feature. Infantile VL may begin either suddenly with high fever and vomiting or insidiously with irregular daily fever, anorexia, weight loss, lassitude, and pallor. When fever is present, double daily spikes are a characteristic sign, with temperatures reaching 40° to 40.6° C (104° F to 105° F). The spleen gradually enlarges, so that by the end of the first month it can be palpated. If the symptoms continue unabated, the spleen may extend to the umbilicus or even into the pelvis. Diarrhea or frank dysentery is not unusual, and blood sometimes is observed. A general bleeding diathesis often becomes evident shortly before death. After several months, if the disease is untreated, patients usually die. Acute fulminant disease is seen more often in infants and young children.

In other cases, the clinical course is more protracted and generally ends fatally after a year or two. In older age groups, the disease tends to assume a more chronic course, with marked emaciation, brittle hair, massive splenomegaly, lymphadenopathy, and a dusky slate-gray complexion. Hyperglobulinemia, leukopenia, and anemia typically are found. As a result of general debility, death often results from concurrent infections such as pneumonia, amebic or bacillary dysentery, malaria, or cancrum oris in more than 90 percent of cases. Infantile VL has been associated with alterations in lipoprotein metabolism.[6] A handful of cases of presumed congenital VL have been reported.[21,64] These infants were born of infected mothers, and in some, evidence of parasitism of the placenta was found.[21] However, whether these cases represent congenital infection or peripartum infection is unclear because sophisticated serologic techniques were not available.

In a study of hormonal disturbances in visceral leishmaniasis, primary adrenal insufficiency was observed in 45.8 percent of patients; low aldosterone/renin plasma ratio in 69.4 person; low daily urinary aldosterone excretion in 61.1 percent; and low transtubular potassium gradient in 68.0 percent. All patients had normal plasma antidiuretic hormone (ADH) concentrations, hyponatremia, and high urinary osmolality. Plasma parathyroid hormone was low in 63 percent; hypomagnesemia was present in 46.4 percent, and increased magnesium excretion factor was present in 100 percent. Primary thyroid insufficiency was observed in 24.6 percent and secondary

thyroid insufficiency in 14.1 percent. Normal follicle-stimulating hormone plasma levels were present in 81.4 percent; high luteinizing hormone and low testosterone plasma levels were present in 58.2 percent of men. Hypothalamus-pituitary-adrenal axis abnormalities, inappropriate aldosterone and ADH secretions, and presence of hypoparathyroidism, magnesium depletion, and thyroid and testicular insufficiencies also were seen.[59]

Cutaneous manifestations of kala-azar are encountered frequently. In India, the dark gray appearance of the skin is known as kala-azar (black sickness). In some cases of inadequately treated VL, a skin condition termed *post–kala-azar dermal leishmaniasis* may ensue. In Indian VL, this complication is encountered in 15 to 20 percent of cases and appears several years after therapy. Individuals with VL, or kala-azar, and individuals with post–kala-azar dermal leishmaniasis (PKDL) are considered to be reservoirs of transmission of *L. donovani* in India.[54] In African disease, PKDL occurs much less commonly, often during therapy in approximately 2 to 3 percent of cases, and it heals spontaneously in a few months. The lesions are characterized by the appearance of hypopigmented, erythematous, or nodular lesions on the skin of the face, chest, neck, and buttocks. At times, the nodular lesions of the face may resemble lepromatous leprosy.[58] The lesions are thought to represent a modified form of *L. (L.) donovani* infection in which the parasites no longer invade the viscera and are localized to the skin. These lesions seem to be related to the host's immune response. This change to dermal tropism is said to coincide with recovery from visceral disease and to disappear with relapse. Infection with *L. (L.) chagasi* causes VL in young children. Atypical CL has been reported in older children with this infection.[7]

Pancytopenia is not unusual. Characteristically, anemia is always evident, with hemoglobin levels below 8 g/dL. Survival of red cells is shortened as a result of several possible factors, including Coombs-positive hemolytic anemia and hypersplenism. Leukopenia of 2000 to 3000 cells/mm^3 typically is found with neutropenia, relative lymphocytosis, an almost total absence of eosinophils, and thrombocytopenia. Serum albumin is usually less than 3 g/dL, and globulin levels (mostly immunoglobulin [IgG]) are often greater than 5 g/dL (5 to 10 g/dL).

Kala-azar has been reported as an important opportunistic infection in patients infected with HIV-1 and not known to have contracted *Leishmania* infection previously. These patients appear to have a more severe and fulminant form of kala-azar. In this regard, inapparent *Leishmania* infection may become evident after immunosuppression, such as chemotherapy for malignant disease. The diagnosis may be particularly difficult to make inasmuch as the findings are often atypical and consist of low-grade fever, fatigue, cough, and gastrointestinal complaints. Certainly in AIDS patients, VL is a recurrent disease that is highly prevalent and whose clinical course is modified by HIV. VL is very prevalent among HIV-1–infected patients in southern Spain, with a high proportion of cases being subclinical.[38] Symptomatic cases appear mainly when severe immunosuppression is present. There is also an association between VL, the male sex, and intravenous drug use. Similarly, atypical visceral disease caused by *L. tropica* was seen in individuals who participated in Operation Desert Storm in the Persian Gulf.[33]

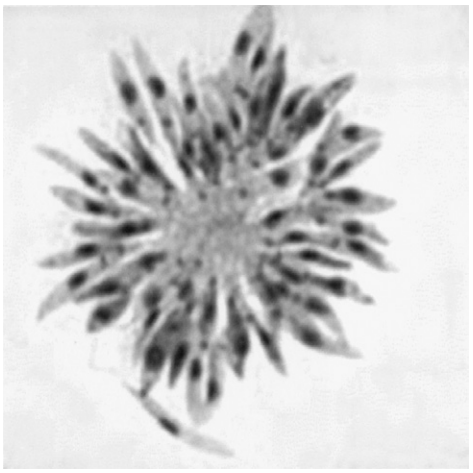

FIGURE 220-8 ■ *Leishmania* sp. promastigotes from culture system.

Diagnosis

VL is diagnosed by finding the organism in stained smears of spleen aspirate,[13] peripheral blood, or bone marrow (see Fig. 220-7). In Indian kala-azar, the parasites may be found regularly in peripheral blood monocytes (i.e., buffy coat), but in the African and Mediterranean forms, they may be difficult to find by this technique. Blood and marrow cultures grown on NNN medium or in Schneider insect medium with 15 to 20 percent fetal calf serum are most useful (Fig. 220-8). Some investigators regard splenic rather than bone marrow aspiration as the most sensitive procedure, although it can be especially hazardous in individuals with a bleeding diathesis. Contraindications include a soft or diffluent, acutely enlarging spleen. Patients with low platelet counts, a prolonged prothrombin time, or both should not undergo the needle biopsy procedure. In children younger than 5 years, splenic aspiration should be performed only by a physician fully experienced in the procedure.

Spleen and bone marrow aspirates should be placed in culture medium and smeared on slides, and saline-diluted aspirates should be inoculated into the peritoneal cavity of hamsters (see Fig. 220-6).

In a study conducted in pediatric patients in the Mediterranean region, antibody detection techniques, the antigen detection in urine (KAtex kit), and *Leishmania* nested polymerase chain reaction (LnPCR) analysis of the blood were useful for diagnosis of the first clinical episode.[16] After treatment, clinical improvement was associated with negative NNN cultures and microscopy of bone marrow aspirate, KAtex test, and LnPCR blood analysis results. New noninvasive techniques tested showed high diagnostic sensitivity. However, LnPCR analysis of the bone marrow was the most sensitive and was able to detect the persistence of parasites and predict potential relapses.[16]

Diagnostic approaches for visceral leishmaniasis have been improved in the last decade with the development of serologic and molecular tests. However, in many parts of the world, a definitive diagnosis still relies on the older parasitologic methods. Recombinant antigens have led to improved performance of serodiagnostic methods. Serology-based tests, rK39 antigen dipstick, and direct agglutination test are highly sensitive methods; however, they fail to distinguish present from past infections. Molecular approaches have become increasingly relevant because of the remarkable sensitivity, specificity, and flexibility in sample selection. Quantitative PCR is a highly sensitive and specific tool used in referral laboratories for detection and assessment of parasite load in VL patients and in monitoring treatment response. This method has the potential to distinguish asymptomatic patients in endemic areas. Techniques such as loop-mediated isothermal amplification offer a reliable molecular diagnostic method for field application.[46,56]

Nonspecific tests detecting the markedly elevated serum globulins such as the formol gel test is helpful in acute disease and is performed readily in the field. Antileishmanial antibodies are usually present and can be used to aid in the diagnosis. The fluorescent antibody test is highly specific, as are the indirect hemagglutination and gel diffusion tests. The complement-fixation test, however, is positive in only 65 to 70 percent of cases. Sera from patients with VL are known to give false-positive results when antibodies to *Trypanosoma cruzi* are present; consequently, in the Western Hemisphere, absorbing out these antibodies may be necessary. Of importance is to recognize that fluorescent antibody titers usually fall after complete cure, so a negative titer often is regarded as a sign of successful therapy. DNA–DNA hybridization tests are being evaluated and promise exquisite specificity and sensitivity for the diagnosis of leishmaniasis.[37] Serologic tests may be positive as a result of past or subclinical inapparent infection. An ELISA that detects antibodies to a cloned recombinant antigen, K39, of *L. chagasi* has been shown to be specific in active VL and could detect antibodies in AIDS patients. A recent study has demonstrated that this test could be applied to field situations.

In HIV-1–infected patients with active VL, the sensitivity of a peripheral blood smear is about 5 percent, because of a high parasitemia in these patients. However, in patients with HIV-1 and subclinical VL, the sensitivity of a routine blood smear is less than 10 percent.[5] Unfortunately, in these patients serology and *Leishmania* skin tests have low sensitivities and are not very helpful. Cultures have proved to be effective in VL patients who are coinfected with HIV-1. The usual diagnostic tests also may be negative in patients with *L. tropica* infection or in otherwise profoundly immunocompromised patients. However, two genomic fragments encoding portions of a single 210-kDa *L. tropica* protein have proved useful for the diagnosis of viscerotropic *L. tropica* infection in Desert Storm patients.[20]

The leishmanin or Montenegro skin test, like the lepromin and tuberculin skin tests, is a measure of delayed hypersensitivity to leishmanial antigen. It consists of 10^6 phenol-killed, culture-grown promastigotes in 1 mL of 0.5 percent phenol in saline. The test is performed like the tuberculin test, that is, 0.1 mL is injected intradermally. A positive result is a palpable area of induration at least 5 mm in diameter in 48 to 72 hours. Because the leishmanin test can be positive in CL or VL, the results must be evaluated carefully. In VL, the test remains negative throughout the period of active disease. Once chemotherapeutic control starts to take effect and immunocompetent lymphocytes are able to respond, the test begins to turn positive.[11] Thus, recovery from kala-azar is characterized by the development of cell-mediated immunity. The change from a negative to a positive leishmanin test in VL is regarded as an important prognostic sign that protective immunity is developing or has developed. Because numerous reports noting positive leishmanin tests in individuals who have had no history of VL have appeared, researchers have postulated that many individuals in an endemic area may become immune by previous inapparent infection.

Prognosis

Untreated VL is fatal in 75 to 85 percent of infantile and 90 percent of adult cases. Properly treated at an early stage, it can be cured in 85 to 95 percent of cases. The prognosis for patients in whom pancytopenia or bleeding diatheses develop or in whom a delayed hypersensitivity skin reaction fails to develop usually is poor.

Treatment

VL generally responds to treatment with pentavalent antimonials such as stibogluconate sodium (Pentostam, Triostam), which is the usual drug of choice in the United States and is available through the Drug Service of the Centers for Disease Control and Prevention.[28] Meglumine antimoniate (Glucantime) is available in French-speaking countries and Latin America.[8] The pediatric and adult dose is 20 mg/kg daily administered intramuscularly or intravenously for 28 days. Treatment can be repeated. In areas where leishmanial parasites may have acquired relative resistance to pentavalent antimonials, such as India, Nepal, and East Africa, extending therapy for more than 4 weeks may be necessary.[31] Side effects occur commonly and include nausea, vomiting, headache, anorexia, and abdominal pain. Elevated levels of serum amylase and lipase, indicative of pancreatitis, are encountered occasionally and can be severe. Electrocardiographic changes, including decreased T wave amplitude and T wave inversion, prolongation of the QTc, and nonspecific ST-T wave changes, are seen. They resolve shortly after therapy is concluded. (Treatment should be discontinued if the QTc interval exceeds 0.5 second.) Deaths, presumably caused by arrhythmias, have been reported in patients who were receiving more than 20 mg/kg/day. Primary antimony resistance, as well as relapses after receiving pentavalent antimony therapy, occurs with all types of VL but is most often encountered with the Indian form. The mechanism of antimonial resistance is unclear.[26] In HIV-infected patients, almost 25 percent fail to respond to antimony therapy and almost 40 percent of responders subsequently relapse.[40,42]

Liposomal amphotericin B (AmBisome) has been approved by the U.S. Food and Drug Administration for the treatment of VL.[39] This compound is taken up by cells of the reticuloendothelial system, where amastigotes reside, and is less nephrotoxic, thereby allowing for higher daily doses with shorter courses of therapy. The approved, recommended regimen for immunocompetent VL patients is 3 mg/kg/day on days 1 through 5 and days 14 and 21. In immunosuppressed and HIV patients, treatment of VL with AmBisome has resulted in an almost 100 percent response rate. However, most of these patients relapse.[40,42] The recommended treatment is 4 mg/kg/day on days 1 through 5, 10, 17, 24, 31, and 38. Without maintenance therapy, almost all of these patients relapse. Because resistance to pentavalent antimonials has developed, amphotericin B is used and is highly efficacious. Several recent studies have used liposomal amphotericin B successfully for the treatment of VL presumably caused by *L. infantum* in immunocompetent children.[35]

Parenteral pentamidine isethionate (Pentam 300) is administered intramuscularly (4 mg/kg is given three times weekly for up to 15 doses, depending on side effects such as hypotension, vomiting, and blood dyscrasias). Pentamidine occasionally may exacerbate diabetes mellitus or precipitate latent diabetes. Shock and liver and renal damage have been reported.

In several clinical trials, miltefosine, an oral alkyl phospholipid agent initially developed as an oral antineoplastic drug, has been used as an effective agent for the treatment of antimony-resistant Indian VL.[29,57] The treatment dose was 2.5 mg/kg/day for 4 weeks.

Patients may require hospitalization for therapy; supportive and corrective measures should be instituted in the event that other infections are present. An occasional patient may be encountered who may require splenectomy to relieve the profound hypersplenism and the resulting anemia. Response to therapy often can be assessed by return of the patient's temperature to normal, a brisk reticulocytosis, a gradual reduction in spleen size, and the reappearance of eosinophils on the peripheral blood smear.

Allopurinol has been used with pentavalent antimonials to treat cases of VL that did not respond to pentavalent antimonials alone. Several reports suggest that recombinant IFN-γ is helpful, along with pentavalent antimonial drugs, in successfully treating this disease. Because assessing whether a cure has been achieved is difficult, patients must be monitored at 6-month intervals for as long as 2 years. Fluorescent antibody titers should be absent by the end of 1 year and complement-fixation titers by 6 to 8 months. If post–kala-azar dermal leishmaniasis occurs, treatment should be reinstituted.

Prevention

Control of VL has many aspects. Sandflies (*Phlebotomus* and *Lutzomyia*) can be eliminated readily by residual spraying. Because sandflies ordinarily do not fly very high, sleeping quarters should be above ground level. Permethrin-impregnated bed nets can be highly effective in preventing sandfly bites. Animal reservoirs, such as infected dogs and rodents, should be destroyed. Early therapy will prevent family and neighborhood transmission. A vaccine against different forms of leishmaniasis should be feasible, considering the wealth of information on genetics and biology of the parasite, clinical and experimental immunology of leishmaniasis, and the availability of vaccines that can protect experimental animals against challenge with different *Leishmania* spp. At the present time, however, no vaccine against any form of leishmaniasis is available for human use. One major obstacle is the lack of a conceived market for human leishmaniasis vaccines. Ninety percent of visceral leishmaniasis occurs in five countries (i.e., Bangladesh, Brazil, India, Nepal, and Sudan). Nonetheless, local studies for vaccine development are ongoing in India and Brazil.

CHAPTER 221

Trypanosomiasis

Lawrence A. Ross • Lynne S. Garcia • Murray Wittner • Herbert B. Tanowitz

AMERICAN TRYPANOSOMIASIS

American trypanosomiasis, or Chagas disease, is caused by the protozoan hemoflagellate *Trypanosoma cruzi*, which was discovered first by Chagas in 1909 in the blood of a seriously ill, wasted Brazilian child with fever, lymphadenopathy, and anemia.[89] The disease, transmitted by reduviid bugs, is limited to the Western Hemisphere and is a major health problem in Latin American countries. Chagas disease is currently identified within 21 countries in the Western Hemisphere; geopolitical, economic, ecologic, and vector-related factors have affected epidemiologic trends of this disease.[93,101] During the preceding decade, cessation of transmission of *T. cruzi* by the main vector, *Triatoma infestans*, has been recognized in several countries, including Uruguay, Chile, Brazil, and Guatemala.[63] In endemic areas, it occurs most commonly in the rural poor who live in an environment with many feral reservoir hosts. Maternal to child transmission and laboratory-acquisition are recognized routes of infection.[28,82] It is established that *T. cruzi* may be transmitted by blood transfusion, organ donation, and congenital infection.[52] In addition, outbreaks attributed to contaminated food have been identified.[72] Indigenous infections have been reported from the southwestern United States, Belize, Guyana, and Trinidad and Tobago[6,57] Chagas disease in some endemic areas is the most important cause of heart disease and may result in serious chronic digestive tract pathology.

Collaborative efforts, including control initiatives in the Southern Cone, Andean, Amazon, and Central America regions have resulted in substantial advances in vector control. An initiative for control of Chagas disease in nonendemic regions was undertaken by the World Health Organization (WHO) in 2007. An estimated 8 to 10 million people are infected, a dramatic decrease from previous projections of 16 to 18 million persons. Further, it is estimated that new cases have diminished from 200,000/year to 40,000/year and deaths from 45,000/year to 12,500/year.[68,97,102] It is estimated that 300,000 infected individuals reside in the United States, largely reflecting immigration patterns from Latin America.[8,58] In certain areas of endemic infection, approximately 10 percent of all adult deaths are caused by Chagas disease. The southern United States, particularly Texas, is identified as having many cases. The geographic distribution of *T. cruzi* infection overlaps that of *Trypanosoma rangeli* (a nonpathogen), the trypomastigotes may be misidentified, and the parasitemia is mild.

The Organism

Although six evolutionary lineages have been identified in *T. cruzi*, *T. cruzi* lineages I and II have been the most widely studied. Before 2005, epidemiologic and immunologic data suggested that chronic infections occurring in Brazil and Argentina were caused primarily by *T. cruzi* II strains. Using polymerase chain reaction (PCR) techniques, this hypothesis has been confirmed, and future studies can establish which strains are responsible for Chagas disease in other geographic locations.[49] A third lineage, termed *T. cruzi* III also exists and is equivalent to the sublineage called TCIIc,[16] thus supporting the distinction of six *T. cruzi* lineages, categorized as TcI to TcVI.

T. cruzi is a pleomorphic, spindle-shaped organism with a quite variable size, depending on the strain. The length of the blood forms (trypomastigote) in humans may vary widely, from 11 to 30 μm, including a free anterior flagellum. Most trypomastigotes assume a "C" or "S" shape, with the nucleus located just anterior to the middle of the cell. Trypomastigotes occur in the blood in two forms, a long slender form and a short stubby one. The nucleus is situated in the center of the body, with a large oval kinetoplast located at the posterior extremity. The kinetoplast consists of a small blepharoplast and a large, oval parabasal body; the kinetoplast often appears to protrude from the cell surface (Fig. 221-1). The kinetoplast contains thousands of mini-circle and maxi-circle DNAs that serve in the synthesis of mitochondrial proteins. A flagellum arises from the blepharoplast and extends along the outer edge of an undulating membrane until it reaches the anterior end of the body, where it projects as a free flagellum. When the trypomastigotes are stained with Giemsa stain, the cytoplasm stains blue and the nucleus, kinetoplast, and flagellum stain red or violet.

Trypomastigotes are ingested by the reduviid bug as it obtains a blood meal. Within a few hours after taking an infective blood meal, short, spindle-shaped forms lacking a free flagellum can be found in the insect's foregut. These forms develop into small epimastigotes that continue to divide and give rise to large (35 to 40 μm) epimastigotes; by the third or fourth day after the blood meal, these organisms can be found attached to the rectal epithelium. By about the fifth day, the epimastigotes have begun to round up and gradually develop into short, stout trypomastigotes, which then proceed to elongate, and by the seventh and eighth days, they become the long,

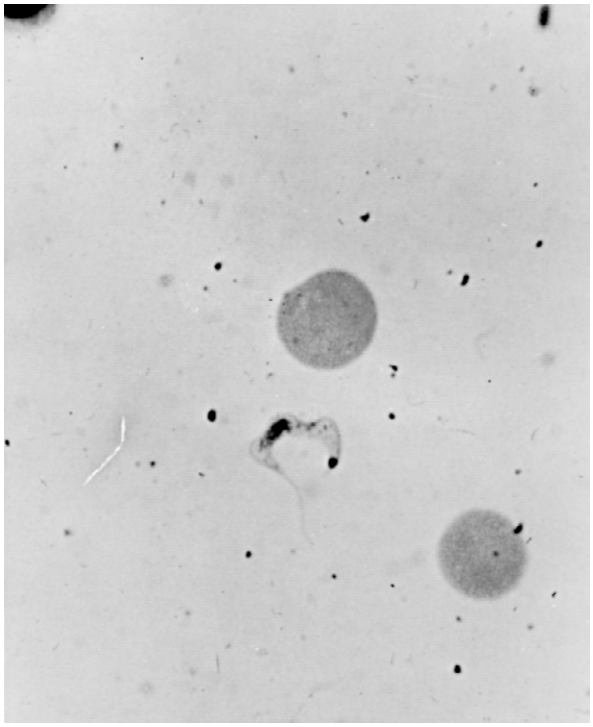

FIGURE 221-1 ■ *Trypanosoma cruzi* trypomastigote forms in a blood smear. Note the large posterior kinetoplast (original magnification ×288).

slender (17 to 22 μm), infective, metacyclic trypomastigotes. After 8 to 10 days, metacyclic trypomastigotes develop from the epimastigotes and are passed in the feces to infect humans when rubbed into the insect's puncture wound or rubbed onto exposed mucous membranes. These forms do not divide again, but are passed out with the feces sometime after the blood meal. There may be 3000 to 4000 organisms per microliter of excreta. Transmission may occur by means of infected insect excreta, and metacyclic forms readily negotiate mucosa, conjunctiva, and abraded or otherwise broken skin (puncture site). Extensive experimental evidence has shown that infection is by contamination rather than insect inoculation.

On invasion of a cell, the trypomastigote loses its flagellum and undulating membrane and divides by binary fission to form an amastigote. The amastigote continues to divide and eventually fills and destroys the infected cell. Amastigote and trypomastigote forms are released from the cell. The amastigote is indistinguishable from those found in leishmanial infections. It is 2 to 6 μm in diameter and contains a large nucleus and rod-shaped kinetoplast that stains red or violet with Giemsa stain. The cytoplasm stains blue. Only the trypomastigotes are found free in the peripheral blood.

When the infective metacyclic trypomastigotes traverse the skin, they invade and multiply locally in many cell types after having transformed into intracellular amastigote forms. Host-cell entry by the parasite is a complex process involving many host and parasite factors. Trypomastigotes released from infected host cells may infect adjacent uninfected cells or enter the bloodstream and lymphatics to infect distant tissues. No tissue is spared from infection, but *T. cruzi* strains may vary in tissue tropism. The cells of the reticuloendothelial system and nervous and muscular (striated and cardiac) systems seem to be particularly vulnerable. In the ensuing weeks, during which time repeated cycles of multiplication, cell destruction, and cell reinvasion have occurred, flagellates enter the bloodstream as trypomastigotes, and the infection becomes disseminated. Trypomastigotes of *T. cruzi* do not divide in peripheral blood; however, the trypomastigotes of *T. rangeli* and the African trypanomastigotes do continue to divide.

Epidemiology

Chagas disease is a zoonosis occurring throughout American continents and involves reduviid bugs living in close association with human reservoirs (e.g., dogs, cats, armadillos, opossums, raccoons, and rodents). The most ubiquitous sylvatic reservoir host is the opossum, *Didelphis*, which is found throughout much of the range of *T. cruzi* in the Americas. Multiple nesting or resting sites of the opossum encompass many types of triatomine habitat. High *T. cruzi* prevalence rates are due partly to the fact that opossums eat triatomid bugs and may transmit infection via anal gland secretions. Sylvatic cycles of *T. cruzi* transmission extend from southern Argentina and Chile to northern California.

The vectors are distributed in rural wooded areas closely associated with feral animal species; humans intervene only occasionally. This infection usually is a zoonosis. Many species have become adapted to houses, however, where they may live in cracks; on roofs, walls, and floors; and beneath seldom-moved objects. Other triatomine species have developed regular visiting habits to human dwellings, but have not taken up residence as yet. Although Chagas disease always has been associated with rural areas and low socioeconomic groups, some vectors have adapted to areas undergoing urbanization. Various suitable hosts that often live close to humans, such as the opossum, may provide the transition between wild and domestic infection. Investigators frequently have observed that domestic animals such as pigs, cattle, goats, and sheep are kept in close contact with the domicile, and that triatomid bugs closely associated with these animals can be carried into the home.

Although 12 species of reduviids occur within the United States, they have not adapted themselves to household habitation. Humans should avoid sleeping in thatch, mud, or adobe houses; bed nets should be used by individuals sleeping in these types of houses. Travelers planning to stay in hotels, resorts, or other well-constructed housing facilities are not at high risk for contracting Chagas disease. Insecticides can be used to kill the vectors and reduce the risk for transmission. The reduviid bug life stages include egg, five instars, and adult. A full blood meal is required for molting to the next stage; development from egg to adult may take a year or longer. Aside from natural transmission via the vector, other modes of transmission include congenital, blood transfusion, breast milk, organ transplantation, laboratory accident, and contaminated food.[10,48] Reported

rates of congenital infection vary substantially, ranging from 1 to 12 percent of infants born to infected mothers.*

Blood transfusion is an important mode of transmission. In many large urban areas of South America, 3 to 15 percent of blood donors were reported to have positive serologic findings. The problem is compounded because blood forms can live for weeks in stored refrigerated blood without losing their infectivity. Concerted efforts to evaluate blood donors for Chagas disease have achieved screening levels of 99 percent in most areas of Latin America.[84] In recent years, immigration from endemic regions to North America, Europe, Australia, and Japan has resulted in increasing recognition of Chagas disease in these nonendemic regions, with concomitant risk for transfusion-associated transmission outside the classic endemic regions.[70,51,83] The prevalence of *T. cruzi* in blood donors in the United States is approximately 1/30,000; transmission from blood transfusion and organ donation have been confirmed.[59] In areas where seroprevalence is high, rather than discarding all positive blood units, laboratories add gentian violet to the units, which are stored at 4°C (39.2°F) for 24 hours before use, to kill the organism.

Ingestion of infected mice by cats or cannibalism among rodents has been shown to transmit the infection successfully. Several reports have indicated the acquisition of infection by humans from infected meat. However, the importance of these routes of infection in maintaining the disease in nature or in humans is unclear. In endemic areas, large numbers of feral and domestic reservoirs of *T. cruzi* exist. Dogs and cats, especially in Brazil and Chile, have been shown to have a high index of infection and are thought to represent important domestic reservoirs. In some areas, armadillos have been implicated. In the United States, naturally occurring Chagas disease has been reported from Louisiana, Oklahoma, and Texas. In addition, the wood rat, raccoon, armadillo, and opossum are important feral hosts.

Pathogenesis and Pathology

When metacyclic trypomastigotes penetrate the skin or mucous membrane, they may be phagocytized by tissue macrophages or actively penetrate other cells (Figs. 221-2 and 221-3).[76] Within the cell, trypomastigotes rapidly transform into rounded amastigotes and division begins (Fig. 221-4). In vitro studies have shown that parasites within macrophage vacuoles may be killed by the cytocidal mechanisms of the host cell, which include nitric oxide. The parasite may escape the parasitophorous vacuole by elaborating a hemolysin and reach the cytoplasm, where it reproduces. Within these cells, large numbers of amastigotes are formed, and within a few days, the greatly distended cells rupture and free trypomastigotes and amastigotes into tissues. They actively invade previously uninfected cells, and the process is repeated.

A nodular swelling, or chagoma, develops at the site of entry (Fig. 221-5). This area soon is infiltrated with macrophages surrounded by lymphocytes, eosinophils, and neutrophils. The process spreads to the regional lymph nodes, where focal lymphadenitis may be seen. Shortly thereafter, blood forms appear and disseminate throughout the body. An acute pathologic condition is caused by the invasion and subsequent destruction of cells by the replicating intracellular parasites. A marked host inflammatory reaction occurs characterized by local accumulation of neutrophils, lymphocytes, and plasma cells. Although any tissue can be involved, cardiac and skeletal muscle and the cells of the reticuloendothelial and nervous systems are infected more frequently.[71]

The myocardium reveals focal myonecrosis, contraction band necrosis, interstitial fibrosis, and lymphocytic infiltration. Interspersed among the degenerating fibers is a marked mixed inflammatory cell exudate, which with time becomes predominantly mononuclear. The course of the acute infection can be quite variable, with severe tissue destruction, or the infection can be silent, with few or no obvious pathologic findings. Nonetheless, the parasites have entered various cells of the body successfully

and have formed pseudocysts, each containing hundreds to thousands of amastigotes (Fig. 221-6). Individuals who recover from the acute episode, including those who have remained asymptomatic, probably harbor these intracellular parasites for the rest of their lives.

The immunology of Chagas disease in experimental animals and humans is very complex. At present, the disease is conceptualized as representing a persistent but variable interaction between *T. cruzi* and the host.[42] Immunologic investigation suggests that both innate immune response (NK cell activity) and adaptive immune responses (cell-mediated response and antibody formation) are apparent in the host response and contribute to tissue injury.[35,76] Cytokines such as interferon-γ and nitric oxide contribute to the intracellular killing of this parasite and to myocardial and gastrointestinal tract dysfunction.

Chagasic heart disease represents the interplay of inflammation and ischemia. During acute infection, foci of myonecrosis, myocytolysis, and vasculitis are observed, along with an inflammatory exudate consisting primarily of leukocytes. Pseudocysts containing amastigotes can be found interspersed among the degenerating fibers. *T. cruzi* gains access to cardiac myocytes by first invading endothelial cells, the interstitial areas of the vascular wall, and the myocardium. Parasites can be seen in and around the endothelium of infected mice. The trypomastigotes pass two basal laminae and two layers of extracellular matrix. Parasite enzymes such as proteases, gelatinases, and collagenases degrade native type I collagen, heat-denatured type I collagen, and native type IV collagen. Proteolytic activities against laminin and fibronectin also have been detected. These enzymes may play an important role in the degradation of extracellular matrix and subsequent parasite invasion.

Degradation of the collagen matrix, evident in acute murine Chagas disease, has been proposed to result in chronic pathologic processes such as apical thinning of the ventricle. When damage such as that caused by ischemia and necrosis occurs, extracellular matrix degradation ensues and leads to slippage of the ventricular layers,

with mural thinning and formation of an aneurysm. Damage to this area of the heart and remodeling of the wall frequently are encountered in chagasic heart disease. Remodeling refers to the structural changes associated with inflammation, necrosis, hypertrophy, and ventricular dilation. In the course of chronic chagasic heart disease, myonecrosis, myocytolysis, and contraction band necrosis are evident. The necrosis results from transient hypoperfusion followed by reperfusion, such as occurs after local spasm of the coronary microvasculature. Focal and diffuse areas of myocellular hypertrophy may be observed with or without inflammatory infiltrates. In other areas, focal fibrosis replacing previously damaged myocardial tissue is evident.

An important feature of chagasic heart disease is a dense accumulation of extracellular collagen that encloses fibers or groups of fibers. All areas of the heart, including the conduction pathways, may be involved. Microvascular involvement, manifested by basement membrane thickening, has been shown. These irreversible changes lead to functional disturbances. The remodeling process results in replacement of cardiac myocytes and cells of the vasculature by fibrous tissue, which leads to thinning of the myocardium and hypertrophy of the remaining cardiac myocytes. Chronic chagasic cardiomyopathy is characterized by focal lymphocytic infiltrates (predominately $CD8^+$), myocyte necrosis, and marked reactive and reparative fibrosis. The role of apoptosis in the pathogenesis of chronic chagasic cardiomyopathy is unclear.

In the chronic stage of Chagas disease, the heart usually is enlarged. The chambers may be dilated and associated with an apical left or right ventricular aneurysm, which rarely ruptures. Mural thrombi, especially of the right atrium and apex of the left ventricle, commonly are seen. They may cause widespread embolization, especially to the brain, lungs, spleen, and kidneys. The myocardium often reveals diffuse fibrosis with small numbers of mononuclear cells scattered throughout, and in many patients, finding parasites in the myocardium may be quite difficult.

The apparent absence of parasites in the myocardium during routine histologic examination in chronic Chagas cardiomyopathy, even in the presence of marked morphologic and functional changes, has engendered much speculation regarding possible pathogenic etiologies. Parasite persistence, autoimmunity, disturbances in the autonomic nervous system, and vascular compromise have emerged as possible important factors. Experimental studies indicate that endothelin-1 and thromboxane A_2, potent vasoconstrictors, and nitric oxide may contribute to the pathogenesis of Chagas cardiomyopathy.[73] In addition, genetic epidemiologic studies suggest that susceptibility to infection and progression to chronic disease may be partly genetically determined. Researchers have estimated that destruction of more than 95 percent of the ganglion cells of the myenteric plexus in the esophagus and colon is required for evidence of megaesophagus and megacolon. In experimental studies, destruction of ganglion cells mediated by inflammatory mediators is the result of parasitic destruction during the acute phase of the disease.

Clinical Manifestations

Clinically, Chagas disease can be viewed as having three phases: acute, indeterminate, and chronic. Seroepidemiologic studies indicate that overt or clinically recognizable disease fails to develop in most individuals infected with *T. cruzi*, and researchers estimate that 99 percent of individuals infected have inapparent or subclinical infection. Most individuals in whom clinical disease develops as a result of natural infection are infants unable to ward off the bite of triatomes, or "kissing bugs," and other young children up to 10 years old. After an incubation period of approximately 7 to 14 days, acute clinical symptoms may begin with anorexia, lassitude, headache, and intermittent or remitting fever with temperatures of 38° to 40.5° C (100° to 104.9° F). In young infants, swelling and edema of Bichat's fat pad may make feeding painful.

Early Disease

Locally, or near the site of initial infection, a characteristic unilateral, painless palpebral edema, often with conjunctivitis, may be recognized. This so-called Romaña's sign, when present in an endemic area (25% to 30% of patients), is highly suggestive of early acute Chagas disease. The edema may be generalized and mistaken for nephrotic syndrome, however, or swelling of the preauricular region may be so severe that it suggests mumps. The edema does not pit on pressure, and the skin is dry. Generalized lymphadenopathy, hepatosplenomegaly, vomiting, diarrhea, and signs of meningeal irritation commonly are encountered. Skin lesions can vary from a generalized maculopapular or morbilliform eruption to urticaria. Neurologic symptoms, found more often in younger infants than in older patients, include focal to generalized seizures.

Acute Stage

Acute-stage symptoms occur in only approximately 1 percent of patients, usually are seen in younger children and are less obvious in older individuals because of the nonspecific nature of the symptoms and the lack of availability of health care. Symptoms generally last 4 to 8 weeks and then may subside, even without therapy. Acute systemic signs occur around week 2 to 3 of infection and are characterized by high fevers, which may be intermittent, remitting, or continuous; hepatosplenomegaly; myalgia; erythematous rash; acute myocarditis; lymphadenopathy; keratitis; and subcutaneous edema of the face, legs, and feet. There may be signs of central nervous system (CNS) involvement, including meningoencephalitis, which has a very poor prognosis. Myocarditis is manifested by electrocardiographic changes, tachycardia, chest pain, and weakness. Amastigotes proliferate within the cardiac muscle cells and destroy the cells, leading to conduction defects and a loss of heart contractility. Death may occur secondary to myocardial insufficiency or cardiac arrest. In infants and very young children with acute Chagas disease, swelling of the brain can develop, causing death.[67] Also, in some areas of

endemic infection, a high frequency of early electrocardiographic abnormalities in children who are seropositive for *T. cruzi* suggests a rapid evolution from infection to disease. Under such conditions, a public health chemotherapy program targeted to this population would be recommended.

During acute infection, echocardiography may reveal abnormal segmental left ventricular wall motion, most commonly in the anterior or apical regions (or both). The overall size of the left ventricle and ejection fraction are typically normal. Fatal acute myocarditis may occur in a few patients. Examination of blood during the acute infection often reveals trypomastigote forms, leukocytosis with a relative lymphocytosis, and an elevated erythrocyte sedimentation rate. Trypomastigotes may be present in cerebrospinal fluid (CSF), even in the absence of neurologic abnormalities. Although most patients recover, apparently without sequelae, 2 to 10 percent may die of severe myocarditis, meningoencephalitis, or an underlying bacterial or viral infection. As the acute stage subsides in 8 to 12 weeks, increasingly fewer parasites can be found in the peripheral blood as antibody levels increase. The disease enters the indeterminate period, and evidence of infection may be detected by special techniques described later. During acute infection, most of the antibody is immunoglobulin (Ig)M. Later, in the indeterminate and chronic stages, antibodies predominantly are IgG. From a global perspective, *T. cruzi* infection is recognized as the most common cause of myocarditis.

Indeterminate Phase

The indeterminate phase of Chagas disease represents the period between acute infection and the onset of chronic signs and symptoms. The duration of this period can span 10 to 40 years, and in most cases, overt clinical disease never develops despite the fact that in asymptomatic individuals, organisms often can be identified by culture or molecular methods and by xenodiagnosis. During the indeterminate phase, electrocardiographic or radiologic abnormalities may not be detectable. However, a minority of patients will have demonstrable abnormalities identified using echocardiography or magnetic resonance imaging modalities.[78,99] Many of these individuals (10% to 30%) eventually experience the serious and potentially fatal chronic phase of the disease. A report from a hospital in Brazil identified Chagas heart disease in 11 percent of patients who died of a cardiovascular cause.[45,99]

The patient may have a subpatent parasitemia and develop antibodies to various *T. cruzi* antigens. Chronic Chagas disease is diagnosed more commonly than the acute disease. The chronic stage may be initially asymptomatic (indeterminate stage), and although trypomastigotes seldom are seen in peripheral blood, transmission by blood transfusion is a serious problem in areas where the disease is endemic. There are regional variations in disease severity, which may account for the geographic differences in morbidity. Approximately 8 to 10 weeks after infection, the indeterminate stage begins, during which the patients do not have any symptoms.

Chronic Stage

Chronic Chagas disease shows close interaction between the parasite and the host, causing many different clinical syndromes. Approximately 30 percent of patients may develop chronic Chagas disease, including cardiomyopathy, megacolon, and megaesophagus. Symptoms of the chronic stage are related to the damage sustained during the acute stage of the disease, the state of the host's immune system, and the inflammatory response. Other contributing factors include the host genetic background, environmental and social factors, the genetic composition of the parasite, and mixed infections and reinfections. The inflammatory response undergoes periods of exacerbation and is probably responsible for neuronal damage, microcirculatory changes, heart matrix deformations, and possible cardiac failure. Selenium deficiency also has been linked with some cardiomyopathies and apparently is a biologic marker for Chagas disease and related to progressive pathology.

Chronic chagasic heart disease occurs insidiously or abruptly with an arrhythmia, dilated congestive cardiomyopathy, thromboembolic phenomena, and sudden death. An apical aneurysm, with or without thrombus formation, is a hallmark of this disease and is commonly found, although not exclusively, in the left ventricle. Although significant major coronary artery lesions are usually absent, several instances of myocardial infarction in individuals with Chagas disease have been reported. Destruction of conduction tissue results in conduction abnormalities.[64] Chronic Chagas disease is now established as predisposing to cerebrovascular ischemic events and may be the initial indication of cardiomyopathy.[25] Microscopically, there is interstitial fibrosis of the myocardium and rare amastigotes; focal infiltrates of lymphocytes, monocytes, and plasma cells are present. Focal neutrophils and occasionally eosinophils may also be seen.

In endemic areas, electrocardiographic abnormalities may suggest chagasic cardiomyopathy. A right bundle branch block alone and a right bundle branch block together with an anterior fascicular block are highly suggestive of chagasic heart disease. These abnormalities have been reported in teenagers and young adults. Premature ventricular contractions and right bundle branch block occur in 50 percent of cases, atrioventricular block of varying degrees develops in about 30 percent of cases, complete atrioventricular block is seen much less commonly, and left bundle branch block is not characteristic. Chest radiographs may reveal cardiomegaly. Heart sounds may be distant, and murmurs of functional mitral and tricuspid insufficiency sometimes are heard. More recently, echocardiography and cardiac magnetic resonance imaging have been used to diagnose and suggest prognosis of chronic chagasic cardiomyopathy.[99] When congestive heart failure ensues, it is usually intractable and difficult to treat. Models have been formulated to identify risk scores predictive of survival

probabilities from Chagas heart disease. Such models may facilitate development of clinical trials for therapeutic intervention.[75]

Megaesophagus and megacolon are the result of destruction of the ganglion cells of the autonomic plexus. Although these complications are not usually fatal except in congenital disease, the marked dilation of the colon and esophagus can be debilitating.[37] Any hollow viscus, including the gallbladder and ureters, can be involved, but esophageal and colonic disease are encountered most frequently. Dysphagia, gastroesophageal reflux, and paroxysmal night coughs, presumably caused by aspiration while sleeping, are associated with megaesophagus; chronic constipation, long-term fecal retention, impaction, and volvulus are observed with megacolon. As megadisease progresses, the thin walls of the esophagus and colon begin to thicken, and the smooth muscle fibers become hyperplastic. There is also a dramatic decrease in the number of ganglion cells of the myenteric plexus. At this point in the disease process, it is very difficult to find amastigotes in either the esophagus or colon.

In some regions, patients with digestive disease have symptomatic chagasic heart disease as well. Wide geographic variation in the prevalence of cardiac and gastrointestinal disease has been noted. In Panama, Venezuela, and Colombia, megaesophagus and megacolon are rarely encountered, whereas in parts of Brazil, both forms of Chagas disease may be seen in the same individual.

Congenital Disease

Congenital Chagas disease is caused by vertical transmission of the infection.[13,18,19,79,92] Pregnant women in endemic areas may experience abortion or placentitis and may give birth to infants with congenital infection associated with prematurity. The risk for maternal-fetal transmission of *T. cruzi* appears to be increased by multiple pregnancies, maternal reinfection, and degree of parasitemia and diminished by adequate maternal innate response.[79,92] Similar rates of maternal-fetal transmission of about 5 percent have been observed in endemic and nonendemic regions.[18] In its acute stage, congenital Chagas disease often resembles the acquired disease. The onset may be at birth or a few months later, with the infant manifesting hepatosplenomegaly, anemia, jaundice, edema, thrombocytopenia, petechiae, tremors, and seizure disorders. The clinical and laboratory findings may resemble those of congenital toxoplasmosis, cytomegalovirus and herpes simplex virus, or erythroblastosis fetalis. Overt clinical disease is observed in 10 to 30 percent of infected newborns and early mortality rates in untreated infants have been reported as 10 percent.[18] Although meningoencephalitis has been observed, it is more likely to be silent. The prognosis of meningoencephalitis in congenital disease is better than in the acquired form of disease. Examination of CSF often reveals trypomastigotes. Necrotic and hemorrhagic lesions of the oral mucosa and skin are thought to represent hematogenously disseminated chagomas. Megacolon and megaesophagus can be present and cause constipation and aspiration pneumonitis.[12,36]

Immunocompromised Patients

Chagas disease has been reported in patients with human immunodeficiency virus (HIV), and neurologic sequelae caused by *T. cruzi* have been major findings.[32,33,60] Transmission of *T. cruzi* has been associated with injecting drug use in HIV-infected persons. Individuals who were previously infected with *T. cruzi* and later became positive for HIV are at risk for reactivation of Chagas disease.[80] These patients develop a severe multifocal or diffuse meningoencephalitis with numerous tissue parasites.[81] Meningoencephalitis is rare in patients without acquired immunodeficiency syndrome (AIDS) and is seen most frequently in immunocompetent children younger than 4 years. Because of the immunodeficiency associated with HIV infections, concomitant infection with *T. cruzi* may be difficult to recognize, particularly in individuals who have moved to areas where the disease is not endemic. *T. cruzi* infection also may have a protracted asymptomatic course in immunosuppressed HIV patients. Although a positive blood smear has been considered the key indicator of Chagas disease reactivation in immunocompromised patients with chronic disease, this finding may occur late, rather than early, in the reactivation process. It has been suggested that *T. cruzi* type I genotype may be associated with cerebral tropism in HIV-infected persons.[20]

Recrudescence of *T. cruzi* infections in immunosuppressed patients, particularly transplantation patients, is concerning. Transplant recipients also can become infected through receipt of infected organs.[27] In endemic regions, transplantation of bone marrow, liver, and kidneys from infected donors is controversial; hearts should not be transplanted. Treatment guidelines for HIV-infected adults and adolescents with Chagas disease have been formulated.[7] In patients with end-stage Chagas cardiomyopathy, heart transplantation is an option that has had variable success. Reactivation of the disease with the development of cutaneous lesions has been seen.[22] Bone marrow transplant recipients also are at risk for Chagas disease because of reactivation or transfusion. Prophylactic treatment of these patients has led to favorable outcomes.

There seems to be a link between *T. cruzi* seropositivity and human T-cell lymphotrophic virus 2 (HTLV-2) infection in studies of the Indians in western Paraguay. In this group, an individual infected with HTLV-2 is 2.28 times more likely to be *T. cruzi*–positive than an HTLV-2–negative individual. The public health significance of these findings is emphasized by the fact that approximately 8 to 10 million people are infected with *T. cruzi* in the Americas, and the frequency of HTLV-2 continues to increase.[46]

Diagnosis

Routine Methods

The diagnosis of Chagas disease should be considered if there is a history of consistent exposure to reduviid bug bites, residence in or travel to areas where the disease is endemic, a laboratory accident or recent blood

transfusion in an area where the disease is endemic, or if cardiac or digestive tract lesions are compatible with Chagas disease. A definitive diagnosis depends, however, on demonstration of the trypomastigotes in the blood, amastigote stages in tissues, or positive serologic reactions. Methods used for examination of blood are similar to the methods used for the diagnosis of African trypanosomiasis. Trypomastigote stages may be detected easily in the blood in young children; however, in chronic disease, this stage is rare or absent except during febrile exacerbations. Trypomastigotes may be detected in blood by using thin and thick blood films or by buffy coat concentration techniques. The most sensitive methods to detect trypomastigotes are concentration techniques, such as the Strout method of buffy coat preparations.[50] With the Strout method, blood is collected without anticoagulant and allowed to clot. The serum is centrifuged at low speed to remove the remaining blood cells and then at a higher speed ($600 \times g$) to concentrate the parasites in the sediment. The stain of choice is Giemsa for trypomastigote and amastigote stages; other blood stains also are acceptable.

Examination of peripheral blood is valuable only during the initial acute disease (6 to 12 weeks) or during chronic exacerbation. Although inoculation of animals with the patient's blood often aids in the diagnosis, this is not a practical approach in most diagnostic laboratories. In chronic stages, the investigator frequently must take 30 to 50 mL of the patient's blood and inoculate numerous cultures to obtain a positive diagnosis. Aspirates, blood, and tissues also can be cultured, which is valuable in detecting low-grade parasitemias. The medium of choice is Novy, McNeal, and Nicolle medium. Cultures should be incubated at 25°C (77°F) and observed for epimastigote stages for 30 days before they are considered negative.

Aspirates from chagomas and enlarged lymph nodes can be examined for amastigotes and trypomastigotes. Histologic examination of biopsy specimens also may be performed. Liver biopsy, bone marrow aspiration, or splenic puncture also can be tried to confirm the diagnosis. Examination of autopsy specimens from immunocompromised patients and patients who die of acute Chagas' disease usually reveals large numbers of amastigotes. Sometimes, xenodiagnosis may be the only means by which organisms can be found. In this technique, laboratory-reared reduviid bugs are permitted to feed on the patient or the patient's fresh blood; subsequently, the bugs are allowed to feed on uninfected guinea pigs. The guinea pigs are examined for trypomastigotes after approximately 45 days. Although 100 percent specific, this test is less than 50 to 80 percent sensitive. If organisms are present in the blood meal, the parasites multiply and are detected in the bug's intestinal contents, which should be examined monthly for flagellated forms over 3 months.

Serologic Tests

Serologic tests can be useful during various stages of the disease. The precipitin test may be positive during the acute episode, whereas complement fixation (Machado-Guerreiro test) is useful for the diagnosis of chronic disease. The most commonly used techniques for serologic diagnosis of chronic-phase Chagas disease include indirect hemagglutination, indirect immunofluorescence and enzyme-linked immunosorbent assay (ELISA). ELISA appears to provide favorable sensitivity and reproducibility.[91] Patients with leishmaniasis, malaria, collagen vascular disease, and syphilis may give false-positive reactions, however. The WHO recommends that at least two techniques be concomitantly positive to establish a diagnosis of Chagas disease.[102] Pregnant women at risk must be screened for Chagas disease, and a venous or umbilical cord blood specimen from the neonate should be evaluated for the parasite. Direct methods (i.e., microhaematocrit) and PCR are quite sensitive during the neonatal and early infancy time frame. Serologic assays based on two different techniques should be performed at least 8 months after birth.[31,39,61]

Polymerase Chain Reaction

Tests using recombinant methods that have the potential for high specificity and high sensitivity have been developed. During chronic infection, the number of circulating parasites is very low, but PCR-based assays can detect low numbers of organisms because the parasite has highly repetitive nuclear and kinetoplast DNA sequences that can be amplified by PCR.[69] During the chronic stage, serologic methods may be the only means to arrive at a diagnosis. The differential diagnosis of chronic chagasic cardiomyopathy includes rheumatic and arteriosclerotic heart disease and cardiomyopathies of other etiologies.

Immunoassays

Immunoassays have been used to detect antigens in urine and sera in patients with congenital infections and patients with chronic Chagas disease.[11] Determination of antigenuria can be valuable for early diagnosis of Chagas disease and for diagnosis of chronic cases in patients with conflicting serologic test results. A highly sensitive and specific chemiluminescent ELISA has been developed for blood bank screening and to monitor patients who are undergoing chemotherapy.[29] Information from screening U.S. blood donors for *T. cruzi* infection has identified autochthonous, chronic infections. This report adds 16 cases to the previously reported 7 cases; currently the estimated prevalence of autochthonous infections is 1/354,000 donors. It is hoped that ongoing studies will be better able to better assess the risk for infection.[23]

Treatment

Although numerous drugs have been tried, including agents used to treat African trypanosomiasis and leishmaniasis, only two medications–benznidazole and nifurtimox–have proved to be effective for therapy of Chagas disease.[56,94] In acute and congenital Chagas disease and infections caused by laboratory accidents, treatment should be administered as soon as possible, even though in some cases symptoms are self-limited. At

present, therapy for Chagas disease is recommended for patients with acute disease, children with congenital infection, and patients in the early phase of chronic disease (in particular, children younger than 15 years of age).[3,87,88] In addition, therapy should be prescribed for patients coinfected with HIV who experience Chagas reactivation. Whether therapy can modify the progression of chronic Chagas disease has not been conclusively shown. However, data published more recently suggest a beneficial effect of therapy in diminishing the risk for progression to severe chronic cardiomyopathy,[98] leading some experts to recommend therapy for adults aged 19 to 50 years with absence of severe heart disease.[9,10] A randomized trial in progress is expected to define more clearly the role of therapy on cardiac outcomes in chronic Chagas disease.[40,65]

Nifurtimox (Lampit), a nitrofurfurylidine derivative, is tolerated better in younger than older patients and should not be used during pregnancy. It reduces the duration and severity of illness and decreases mortality resulting from acute and congenital Chagas disease. Reversible gastrointestinal, cutaneous, and neurologic adverse effects are common. Treatment success varies from one country to another, possibly indicating differences in the susceptibility of strains of *T. cruzi*. There is no indication that treatment of patients with chronic Chagas disease is beneficial. Nifurtimox must be taken orally for prolonged periods, and severe side effects can occur, including abdominal pain, nausea, vomiting, anorexia, and neurologic symptoms. Nifurtimox is available in the United States from the Parasitic Drug Service of the Centers for Disease Control and Prevention. It is supplied in 30-mg and 120-mg tablets. The usual dose for adults is 8 to 10 mg/kg body weight per day. For adolescents (11 to 16 years of age), it is 12.5 to 15 mg/kg/day, and for children (1 to 10 years of age), the dose is 15 to 20 mg/kg/day. It is given in four divided doses daily for 90 to 120 days. This drug has many untoward reactions, including abdominal pain, nausea, vomiting, anorexia, restlessness, disorientation, insomnia, twitching, paresthesia, polyneuritis, and seizures. Skin reactions also may be observed.

Benznidazole (Rochagan) is similar to nifurtimox and seems to have similar efficacy. Some researchers consider it to be tolerated well, with fewer adverse reactions. It is used extensively in Brazil at 5 mg/kg/day for 30 to 120 days in two divided doses (adult dose). For children up to 12 years of age, the dose is 10 mg/kg/day in two doses for 30 to 90 days. Bone marrow depression and peripheral neuritis have limited its use, however. Additional chemotherapeutic agents are urgently needed and are under investigation.[93,77]

Interferon-γ has been used in conjunction with drug therapy because experimental data suggest that it is a useful adjunct in treatment by activating macrophage killing. Allopurinol and antifungal drugs have been suggested as alternatives in some patients. Patients with chronic chagasic cardiomyopathy may be helped for a varying period by implantation of a cardiac pacemaker, but the congestive heart failure is often refractory to cardiac glycosides and vasoactive drugs. More recently, inhibitors of angiotensin-converting enzymes have been advocated to reduce cardiac remodeling in these individuals. Heart transplantation also has been performed for the management of chronic cardiomyopathy. The use of high-fiber diets, occasional laxatives, and enemas may assist in the management of megacolon. When these measures fail, surgical resection may be required. Megaesophagus is usually amenable to therapy consisting of a combination of diet and dilation of the esophagogastric region. In more severe disease, various surgical procedures have been used with variable success to relieve the symptoms of achalasia.

Prevention

A strategy for elimination of Chagas disease, with four core components, was formulated by the WHO in 2007. The components include (1) vector control, (2) screening of blood donors in endemic countries, (3) detection and treatment of congenitally infected patients, and (4) treatment of all infected children and all patients with acute disease.[103] Regular insecticide spraying programs with benzene hexachloride could reduce transmission of the infection, at least around domiciles. Proper screening and improved housing for individuals in endemic areas also help reduce transmission. In endemic areas, thorough screening of blood donors attenuates the risk for transmission via transfusion. In 2010, the U.S. Department of Health and Human Services published guidelines for use of serologic tests to reduce the transmission of *T. cruzi* via blood donations.[96]

The development of a chemoprophylactic agent or vaccine holds the best hope for prevention and subsequent eradication of Chagas disease. Vaccine development is challenged by the recognition that host response to *T. cruzi* infection is characterized as inadequate.[26]

As previously noted, transfusion-acquired disease is a major public health problem in endemic areas. Treatment of blood with gentian violet inactivates the parasite.

Travelers to the Americas should be counseled regarding the transmission risks for Chagas disease, as well as the protective benefit provided by use of pyrethroid-impregnated insect nets when sleeping in unmortared cabins.[40,41]

AFRICAN TRYPANOSOMIASIS

African sleeping sickness is caused by two morphologically identical subspecies of hemoflagellate protozoans: *Trypanosoma brucei gambiense*, the cause of West African or Gambian sleeping sickness, and *Trypanosoma brucei rhodesiense*, the cause of East African or Rhodesian disease. Although these parasites produce similar disease, the Gambian form is usually chronic and evolves slowly, often over many years, and ends fatally if untreated, whereas the Rhodesian form is characterized by being acute, usually killing the host in a matter of weeks or months.[1] Recent findings have indicated the presence of human trypanotolerance in *T. b. gambiense* infections, now considered a major issue for future research.[55] These diseases exist wherever the various species of *Glossina*, the tsetse fly, are found. The completion of the *T. brucei* genome should facilitate greatly the discovery of new

drug targets and genetic markers.[17] The WHO has identified human African trypanosomiasis (HAT) as well as Chagas disease, leishmaniasis, and Buruli ulcer as neglected tropical diseases requiring innovative and intensified disease management.[104]

The Organism

T. b. gambiense and *T. b. rhodesiense* are pleomorphic flagellates 15 to 30 μm in length × 1.5 to 3.5 μm in breadth. In Giemsa-stained blood smears, they may appear long and slender with an undulating membrane and free anterior flagellum or appear short and broad without a free anterior flagellum. No intracellular forms exist. At various stages of disease, trypomastigote forms may be found in the peripheral blood, lymphatics, lymph nodes, CSF, and neural tissue. Although the two species are morphologically indistinguishable and share major biochemical features, isozyme and molecular analysis has shown substantial variation among species, particularly regarding clinical disease. In addition, the two species maintain separate biologic characteristics, especially with regard to virulence in cross-inoculation experiments. Humans are the only important reservoir host for *T. b. gambiense*, whereas *T. b. rhodesiense* naturally infects wild game animals.

The haploid genome size of *T. brucei* spp. is approximately 40 Mb, with 14 percent variation within the same subspecies and 29 percent variation among different subspecies. Homologous chromosomes, when probed by Southern blot, can differ in size by 20 percent. In addition to the large chromosome pairs, *T. brucei* has approximately 100 linear mini-chromosomes ranging in size from 50 to 150 kb. These mini-chromosomes contain transcriptionally silent copies of variant surface glycoprotein (VSG) genes. *T. brucei* has approximately 1000 genes capable of coding for *VSG* genes; these genes are switched at a rate of 10^{-2} to 10^{-6} switches per generation, which serves as the main mechanism of immune evasion for *T. brucei*.[43] Only one VSG expression site is active at any given time. Studies comparing homologous nuclear genes between *T. cruzi* and *T. brucei* have shown large evolutionary divergence in codon usage. Comparison of the nuclear small-subunit and large-subunit rRNA gene sequences yields genetic distances comparable to that between plants and animals.

Within the male and female insect vector, the tsetse fly, the blood meal settles in the posterior portion of the midgut and organisms multiply by binary fission for approximately 7 to 10 days. The slender trypomastigotes migrate anteriorly to the foregut, where they remain for the next 2 to 3 weeks. They next move further forward and finally enter the salivary glands, in which they transform into epimastigote forms—forms in which the kinetoplast has migrated just anterior to the nucleus—and continue to replicate. After multiplication cycles, they transform into infective metacyclic trypomastigote forms, which are the small, broad or "stumpy" forms that lack a free anterior flagellum. When next feeding, the infective tsetse fly may inoculate thousands of these infective trypomastigotes into the bite wound. The entire life cycle of the tsetse fly spans 15 to 35 days. A single tsetse fly can be infected with multiple species of trypanosomes and remains infected for life. Within the human host, trypomastigotes multiply by binary fission in blood, lymph, and extracellular spaces. The CNS eventually is invaded, at which time multiplication continues unabated. Transmission by blood transfusion, hypodermic needle, other insects, and congenital transmission has been reported.

Epidemiology

African sleeping sickness (*T. b. gambiense* and *T. b. rhodesiense*) and veterinary trypanosomiasis caused by *T. brucei* subgroup parasites are responsible for much human suffering and economic loss. Factors that have historically contributed to disease resurgence include socioeconomic unrest resulting in population shifts of animal reservoirs, insufficient financial allocations, emergence of drug-resistant parasitic strains, climatologic alterations, and altered susceptibility of populations at risk.[55] Substantial efforts by the WHO in collaboration with national programs and public-private partnerships, as well as with contributions from nongovernmental organizations in the 21st century have resulted in diminishing the number of new cases.[105] Because the larval stages of the tsetse fly are vulnerable to desiccation, *Trypanosoma* spp. are restricted to an area spanning 10 million km^2 south of the Sahara, encompassing 200 separate foci from 36 countries, where the annual rainfall exceeds 500 mm (20 inches). The most recent reports indicate that, in 2009 and 2010, fewer than 10,000 new reported cases were identified; currently, the estimated number of new cases is approximately just under 10,000/year.[106] *T.b. gambiense* is endemic in 24 nations of west and central Africa and is the reported cause of HAT in more than 90 percent of cases; *T. b. rhodesiense* is endemic in 13 nations in eastern and southern Africa. The recent observation that Uganda harbors both forms of HAT is of great concern because control of HAT requires different strategies for the two parasites; emergence of geographic overlap would add greatly to costs.[47,74,106] The Gambian form occurs mainly in the western portion of tropical Africa, with focal incursions eastward north of Lake Victoria into the Sudan. *Glossina palpalis* is the main tsetse fly vector, although other related species, such as *Glossina tachinoides* and *Glossina fuscipes*, are implicated as well.

Although *T. b. gambiense* can infect various mammals, humans seem to be more susceptible and maintain a high enough parasitemia to sustain the fly-human-fly cycle. The prolonged chronicity of Gambian disease with infectious individuals continually exposed to tsetse flies undoubtedly helps sustain the disease. Asymptomatic carriers of the infection also may be an important factor in maintaining the disease in a community. Among the important factors that may limit Gambian infection to humans is the transient and low parasitemia that results from an infective tsetse fly bite in mammals, usually ungulates. Researchers have observed that Gambian disease typically is sustained only when a close and

repeated relationship exists between humans and tsetse flies. The practical result of all this is that West African sleeping sickness is maintained by members of the *G. palpalis* group of tsetse flies that use or prefer human blood almost exclusively.

In contrast to Gambian disease, *T. b. rhodesiense* infection generally is maintained in wild mammals. The fly-human-fly cycle tends to be unimportant inasmuch as the severe nature of the disease usually quickly removes acutely ill humans as an infective source. The intervention of wild game animals, in which the disease tends to be less acute and whose blood seems to be more attractive, appears to have relegated humans to an occasional or facultative host for *T. b. rhodesiense*. The *Glossina morsitans* group of tsetse flies that inhabit the dry East African savannah readily feed on wild ungulates, especially the bushbuck, *Tragelaphus scriptus*, and the hartebeest, *Alcelaphus buselaphus*. Occasionally, Rhodesian disease may reach epidemic proportions, and during these epidemics, direct human-fly-human cycles may occur.

In endemic countries there tend to be regions where both infected and parasite-free tsetse flies are found, A disease focus can be as limited as a single village or can encompass an entire region, and epidemics tend to be followed by extended periods of endemicity. It is estimated that only 10 percent of new cases are identified or treated. In some endemic areas, HAT is the leading cause of death, even when considering the mortality rate caused by HIV and AIDS.

All age groups are susceptible to infection. The factors that influence human prevalence rest more on occupational exposure to suitable tsetse flies and the flies' breeding and feeding habits. Young men are found to be infected most frequently. During epidemics, all groups are infected, however, and mechanical transmission probably occurs. Tourists on safari are possibly at risk. In that regard, reports of African trypanosomiasis in Europe, the United States, and Australia have been increasing, although fewer than 50 cases/year of human African trypanosomiasis are diagnosed outside of Africa.[95]

Pathogenesis and Pathology

The metacyclic infective trypomastigote forms are inoculated by the tsetse fly into the skin, where they multiply at the inoculation site. A characteristic, hard, sometimes painful chancre develops. By approximately the 10th day, long slender forms are found in the bloodstream and lymphatics, and for the next several days, their numbers increase logarithmically. Soon thereafter, the organisms nearly disappear from the bloodstream as a result of immune lysis, only to reappear again.

The interval between waves of parasitemia may vary from 1 to 8 days, with clinical symptoms accompanying each bout of parasitemia. These parasitemic waves can be accounted for by the highly developed antigenic variation strategy of the parasite. The trypomastigote is covered with viral coat protein VSG, and with each peak of parasitemia, a predominant variable antigen type is displayed by the organism. The specific antibody response to VSG leads to the destruction of parasites that display the predominant variable antigen type or homotype. Numerous heterotypes are found within each population of parasites, one of which, not recognized by the host's immune system, becomes the next homotype. The parasite in each successive wave of parasitemia bears a different variable antigen type. A single trypomastigote may contain 1000 genes, each encoding for a specific VSG. Each successive parasitemic wave represents a new antigenic variant that has emerged to elude the host's antibody response to the previous antigen.

As a result of successive waves of immune lysis and parasitemia, a marked early humoral antibody response, predominantly involving IgM, is seen regularly. *In an immunocompetent host, the absence of elevated IgM levels in serum rules out trypanosomiasis.* These macroglobulins contain not only antitrypanosomal antibodies, which are directed against the surface antigens, but also a variety of other antibodies such as heterophile and rheumatoid factor. Researchers have shown experimentally that because of polyclonal B-cell activation, many antibodies are produced to a wide variety of antigens, including brain-specific autoantibodies directed against myelin basic protein, gangliosides, and cerebrosides. Circulating immune complexes have been reported regularly and may be responsible for the glomerulonephritis, hypocomplementemia, and hemolytic anemia that often accompany acute and chronic disease. Cell-mediated immunity also is important in African trypanosomiasis, and increased production of nitric oxide may be important in depression of T-cell responsiveness and generalized immunodepression.

The main pathologic lesions involve the posterior cervical, submaxillary, supraclavicular, and mesenteric lymph nodes and the CNS. The lymphatic tissue usually reveals generalized hyperplasia with diffuse proliferation of lymphocytes. Later, the nodes may become small and fibrotic; however, they initially are markedly hemorrhagic and contain large numbers of trypomastigotes. The CNS remains normal until invaded by organisms, but then a progressive chronic leptomeningitis develops. The brain becomes edematous, and prominent perivascular cuffing by glial cells, lymphocytes, and plasma cells is present. When the latter become vacuolated with pyknotic nuclei, they often are referred to as the morula cells of Mott and Marshalko. Organisms often can be found in brain tissue in proximity to vessels and may be detected in CSF. Glomerulonephritis, myocarditis, pericardial effusion, pulmonary edema, and hypoplastic bone marrow with associated anemia may be seen.

The pathogenesis of the neuropsychiatric manifestations is not understood. More recent experimental studies suggest that changes in levels of brain neurotransmitters; deposition of immune complexes; and alteration in production of prostaglandin, cytokine, and nitric oxide may account partly for these behavioral changes.[2,85]

Clinical Manifestations

The clinical manifestations of *T. b. gambiense* and *T. b. rhodesiense* disease are similar except that Rhodesian infection is a more fulminant, acute disease that may run

its course in several weeks to 6 to 9 months, whereas Gambian infection may last for years. Typically, the incubation period in Rhodesian infection is brief (3 to 21 days), whereas the onset of symptoms with Gambian infection may be delayed for several weeks or years. Approximately 1 week after infection and at the site of the tsetse fly bite, a hard and painful chancre sometimes appears and lasts several weeks. During the early stages, when recurrent bouts of fever may be the only symptom, the blood and lymphatics primarily are involved, and infection often is mistaken for malaria, especially if a chancre is not obvious or a history of exposure to tsetse flies is not obtained. The period of intermittent fever may last months to years with Gambian infection. During this time, persistent headache and tachycardia often are encountered, and a circinate erythematous rash or erythema multiforme sometimes is noted. The fever abates gradually.

In many patients, characteristic posterior cervical lymphadenopathy becomes evident (Winterbottom's sign). The nodes are nontender and attain a diameter of approximately 1 cm. They tend to become small and fibrotic in approximately 6 months.

Signs of CNS invasion often develop in untreated patients with Gambian disease. The initial signs and symptoms of neurologic involvement can be difficult to assess. They may consist of alterations in behavior or personality (or both) that eventually may be manifested as a severe psychosis. Severe headache, loss of nocturnal sleep, and a feeling of impending doom typically are described. Next, progressive mental deterioration may occur, and with unrelenting deterioration, patients become incapable of caring for themselves. Tremors, especially of the tongue, hands, or feet, and generalized or focal convulsive episodes may occur. Almost any neurologic or psychiatric manifestation can be seen, and with progressive mental deterioration, patients finally lapse into a coma and die.

During the final period of the disease, patients often die of concurrent infections such as bacterial pneumonia, amebiasis, and malaria. Wasting and malnutrition are a large component of the progressive deterioration in these patients. Sleeping sickness can be a difficult disease to diagnose early in young children. It usually is found only after a child is evaluated for obtundation, seizures, or psychomotor retardation.[21,67]

T. b. rhodesiense produces a more rapid, fulminating disease than *T. b. gambiense*. Fever, severe headaches, irritability, extreme fatigue, swollen lymph nodes, and aching muscles and joints are common symptoms. Progressive confusion, personality changes, slurred speech, seizures, and difficulty walking and talking occur as the organisms invade the CNS. The early stages of the pathologic process parallel those of *T. b. gambiense* infections; however, the disease progresses more rapidly, such that death may occur before there is extensive CNS involvement, even though CNS invasion occurs early. The incubation period is short, often within 1 to 4 weeks, with trypomastigotes being more numerous and appearing earlier in the blood. Lymph node involvement is less pronounced, and Winterbottom's sign may be absent. Febrile paroxysms are more frequent, and the patients are more anemic and more likely to develop myocarditis or jaundice. Some patients may develop persistent tachycardia, and death may result from arrhythmia and congestive heart failure owing to pancarditis.

Second Stage

The clinical symptoms and signs of patients with second-stage human African trypanosomiasis are described for a large cohort ($N = 2541$) of patients treated in a prospective multicenter, multinational study.[15] Special emphasis was given to the influence of disease stage (i.e., duration and number of white blood cells in CSF) and patient age on the clinical picture. Although the frequencies of symptoms and signs varied greatly among centers, the clinical picture of the disease was similar for all countries. Headache (78.7%), sleeping disorder (74.4%), and lymphadenopathy (56.1%) were the most frequent symptoms and signs, and they were similar for all stages of the disease. Lymphadenopathy tended to be highest in the advanced second stage (59%). Neurologic and psychiatric symptoms increased significantly, with the number of white blood cells in the CSF indicating the stage of progression of the disease. Pruritus was observed in all stages and increased with the number of white blood cells in CSF from 30 to 55 percent. In children younger than 7 years of age, lymphadenopathy was reported less frequently (11.8% to 37.3%) than in older children or adults (56.4% to 61.2%). Fever was reported most frequently in children 2 to 14 years of age (26.1% to 28.7%), and malnutrition was observed significantly more frequently in children of all ages (43% to 56%) than in adults (23.5%).

Diagnosis

Diagnostic options for human African trypanosomiasis are limited in field settings.[30] Even in field settings, however, positive results from screening assays, such as the card agglutination test, must be confirmed by demonstration of the parasite. Absence of confirmatory testing may lead to unnecessary administration of toxic drugs.[53] It is clear that substantial progress is needed to greatly improve diagnostics for point-of-care use.[66]

Routine Methods

As indicated earlier, a definitive diagnosis can be made only by finding trypanosomes in blood and bone marrow smears, in lymph node aspirates in early or acute disease, and in CSF in late or chronic disease.[100] For examination of thick and thin smears and the buffy coat, 10 to 20 mL of citrated whole blood or the sediment from 5 mL of centrifuged CSF is essential. Numerous microscopic techniques, including capillary tube centrifugation, quantitative buffy coat examination, miniature anion-exchange centrifugation, density gradient centrifugation, and acridine orange staining, have been used to enhance parasite detection. Culture or animal inoculation, or both, is sometimes the only successful means of making a diagnosis. In advanced CNS disease, lymphocytosis and elevated IgM are detected in the CSF.

Serologic Tests

A serologic diagnosis of African trypanosomiasis usually depends on detection of high levels of nonspecific serum IgM. Detection of specific antibody by indirect fluorescent antibody is helpful, especially when the serum is tested with trypanosomes of the homologous human species. Tests to determine antibody levels include the card agglutination trypanosomiasis test, rapid latex agglutination test, indirect immunofluorescence test, and ELISA. Direct agglutination and a microscale version of ELISA are highly reliable methods for making a specific diagnosis of trypanosomiasis.[4]

Polymerase Chain Reaction

Antigen-detection and PCR tests have been developed to detect circulating parasites.[34] The development of a peptide nucleic acid fluorescence in situ hybridization probe seems to offer an excellent diagnostic tool. By combining this test with a cytospin step, the limit of detection from blood can be improved to 5 parasites/mL, a level of sensitivity that equals an optimal PCR detection limit on blood specimens. A newer PCR technique targets the gene encoding the small ribosomal subunit to identify and differentiate all clinically important African trypanosome species and some subspecies. This method seems to be more economical, simple, and sensitive than some other screening methods and yields more detailed information.[34]

Immunoglobulin Levels

In advanced, untreated sleeping sickness, the IgM level in CSF often is elevated, but it has no relationship to the presence of trypanosomes in CSF. After successful treatment, the IgM level declines gradually and disappears after approximately 1 year. However, if 1 year after therapy a constant high level is present, or an abrupt increase in IgM occurs, relapse should be suspected. Nonetheless, the IgM level should not be used as the sole method to arrive at a diagnosis or prognosis.

The differential diagnosis of African trypanosomiasis includes many diseases, but chronic relapsing fever associated with enlarged cervical lymph nodes in an individual who has been to Africa is suggestive. As indicated earlier, considering diseases such as malaria, syphilis, lymphoma, visceral leishmaniasis, and leprosy is not unusual. Later, encephalitis of other etiologies must be excluded. An important diagnostic feature is the frequent finding of a strikingly elevated erythrocyte sedimentation rate, which is a reflection of the markedly increased serum macroglobulins.

Molecular Dipstick

The development and the first-phase evaluation of a simple and rapid test (human African trypanosomiasis–PCR–oligochromatography) for detection of amplified *T. brucei* DNA has been reported more recently.[38] Through hybridization with a gold-conjugated probe (oligochromatography), PCR products are visualized on a dipstick. Visualization is simple and takes only 5 minutes. Controls for the PCR and for DNA migration are incorporated into the assay. The lower detection limit of the test is 5 fg of pure *T. brucei* DNA. One parasite in 180 μL of blood is still detectable. Sensitivity and specificity for *T. brucei* were calculated at 100 percent when tested on blood samples from 26 patients with confirmed sleeping sickness, 18 negative controls (nonendemic region), and 50 negative control blood samples from an endemic region. Human African trypanosomiasis–PCR–oligochromatography is a promising new tool for diagnosis of sleeping sickness in laboratory settings.

Animal Inoculation and Culture

T. b. gambiense isolation in small laboratory animals is usually unsuccessful; in contrast, *T. b. rhodesiense* readily infects animals. Cultivation is not practical for most diagnostic laboratories, but is more successful than animal inoculation.[50]

Prognosis

If therapy is initiated before significant CSF involvement, the outcome is usually favorable. Untreated infection often ends fatally.[54] Patients with severe brain inflammation at time of diagnosis of second-stage disease are at substantial risk for treatment failure. Assessment of pretreatment as well as posttreatment CSF white blood cell counts, IgM titers, and protein concentrations may allow accurate prediction of treatment failure.[62]

Treatment

All drugs currently used in the treatment of African trypanosomiasis are toxic and require prolonged administration. Treatment should be started as soon as possible and is based on the patient's symptoms and laboratory findings. The choice of antiparasitic drug depends on whether the CNS is infected.[56] Pentamidine isethionate or suramin can be used when the CNS is not infected. The main chemotherapeutic agents for human trypanosomiasis are pentamidine and suramin for early-stage disease. Treatment options have expanded for second-stage HAT. Melarsoprol has been used since 1949. Eflornithine, which is effective only against *T. b. gambiense*, was accepted for second-stage therapy in 1990. The combination of nifurtimox and eflornithine was introduced in 2009 after clinical documentation of noninferiority to eflornithine monotherapy with identified safety and ease of administration advantages. This therapeutic combination is now accepted for treatment of *T. b. gambiense* and is included in the WHO List of Essential Medications.[107]

Pentamidine Isethionate

Pentamidine is a water-soluble aromatic diamidine that has been in use for nearly 60 years. It is administered as either the isethionate form (Pentam 300) or methanesulfonate (Lomidine). The dose is 4 mg/kg/day for 10 days

for adults and children. Pentamidine is effective against early-stage *T. b. gambiense* infection, but less effective against *T. b. rhodesiense* infection and ineffective against late-stage disease. African trypanosomes have a nucleoside (adenine/adenosine: P_2) transporter that takes up pentamidine, which results in concentrations of the agent many times that in plasma. Although laboratory-induced resistant strains seem to have reduced transport properties, naturally derived clinical isolates seem to have retained transport, indicating that most resistance may be caused by alteration of a metabolic target, rather than drug uptake. Pentamidine isethionate does not cross the blood-brain barrier and is administered intramuscularly; side effects include an immediate hypotensive reaction, nausea, vomiting, and Herxheimer-type (inflammatory) reactions.

Suramin

Suramin is a sulfonated naphthylamine that has been used successfully against early-stage sleeping sickness caused chiefly by *T. b. rhodesiense*. It was first used in 1922 and was developed from the closely related azo dyes trypan red and trypan blue. Suramin is administered intravenously. The adult dose is 100 to 200 mg (test dose), then 1 g on days 1, 3, 7, 14, and 21. The pediatric dose is 20 mg/kg on days 1, 3, 7, 14, and 21. Suramin has an extremely long half-life in humans (44 to 54 days), which is the result of avid binding to serum proteins. Suramin binds to many plasma proteins, including low-density lipoprotein, which trypanosomes avidly bind and endocytose as a result of specific membrane receptors. Low-density lipoprotein is a prime source of sterols for bloodstream trypanosomes. Suramin is taken up as a protein complex and has been shown to inhibit all the glycolytic enzymes in *T. b. brucei* in low concentrations, which in most cases are severalfold lower than for the corresponding mammalian enzyme. Suramin also has been found to affect thymidine kinase and dihydrofolate reductase.

Suramin (Bayer 205), a diamidine, also is effective in treating the hemolymphatic stage and CNS disease of *T. b. gambiense*. When suramin is used, a test dose should be given to the patient to ensure the drug can be tolerated. It should not be given to patients with renal disease, and if protein, red blood cells, or casts are detected in the urine, treatment should be stopped. Suramin is given intravenously; its side effects include nausea, vomiting, loss of consciousness, seizures, pruritus, edema, and hepatitis. Although rare, fatalities have been reported during suramin therapy. Suramin can be obtained under an investigational new drug protocol from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, Georgia, 30333; 404-639-3670 (evenings, weekends, or holidays: 404-639-2888).

Melarsoprol

Melarsoprol (mel B; Arsobal) is an arsenical created by the efforts of Freidheim in the late 1940s. His initial compound, melarsen oxide, *p*-(4,6-diamino-*s*-triazinyl-2-yl) aminophenyl arsenoxide, was complexed with dimercaptopropanol (British antilewisite) to form a less toxic complex, melarsoprol. Until 1990, it was the only agent available for curing late-stage (CNS) disease of East African and West African origin. Usually, each series is followed by a week interval before the next series. Melarsoprol is insoluble in water and must be dissolved in propylene glycol. It must be given intravenously; otherwise, it induces a severe localized inflammatory reaction. This drug is administered intravenously. The adult dosing schedule is 3.6 mg/kg at 3 days. This is followed in 1 week with 3.6 mg/kg/day for 3 days. This schedule is repeated after 10 to 21 days. The pediatric dose is 18 to 25 mg/kg total over 1 month; the initial dose is 0.36 mg/kg at intervals of 1 to 5 days for a total of 9 to 10 doses.

Side effects include nausea, vomiting, encephalopathy, and exfoliative dermatitis. Melarsoprol has been used for CNS involvement for years; however, relapse occurs in 6 percent of patients. Arsenic-related encephalopathy occurs in 10 percent of patients, and prednisolone treatment may help reduce the incidence. The mortality resulting from this side effect depends on whether supportive treatment is given, but it is often greater than 50 percent. Resistance to melarsoprol by *T. b. gambiense* and *T. b. rhodesiense* has been noted.

Reactive arsenical-induced encephalopathy is an important toxicity of melarsoprol and is followed by pulmonary edema and death within 48 hours in more than half the cases. The incidence of reactive arsenical-induced encephalopathy has been estimated at 2 to 10 percent. In one clinical study, the coadministration of steroids significantly reduced the incidence of reactive arsenical-induced encephalopathy–related deaths during therapy with melarsoprol. Although the mechanism of action of melarsoprol has been studied extensively, it still remains unclear.[1] Clinical signs and symptoms of African trypanosomiasis must be differentiated from those of reactive arsenical encephalopathy, a complication of treatment with melarsoprol.

Eflornithine

Eflornithine (DL-a-difluoromethylornithine [DFMO]) is an enzyme-activated inhibitor of ornithine decarboxylase, the lead enzyme of polyamine biosynthesis. DFMO was developed as an antitumor agent. After initial testing in model infections, DFMO was studied extensively in human trials in Africa, with some trials in Europe and the United States. The standard treatment regimens resulting from trials indicate that DFMO is more than 95 percent active when given intravenously at 400 mg/kg/day in four doses every 6 hours for 14 days. In these studies, DFMO cured children and adults, patients with melarsoprol-refractory strains, and patients with late-stage disease.[44] The short plasma half-life of DFMO necessitates constant dosing when given as an intravenous drip. The most frequent toxic reaction was reversible bone marrow suppression, which was reversed by reducing the dosage.

The major drawbacks of DFMO are its cost and the duration of treatment and availability. DFMO is not trypanocidal and depends on a functional immune system to rid the host of nondividing forms. It is curative for laboratory infections of *T. b. brucei* and *T. b. gambiense*, but not all strains of *T. b. rhodesiense*. The reason for this selectivity is not evident, although it is not caused by uptake of DFMO because the drug enters by passive diffusion, not transport. DFMO treatment leads to intracellular concentrations of approximately 5 mmol/L, an increase of approximately 50-fold over untreated parasites. The basis for DFMO selectivity lies in the rapid turnover of the mammalian enzyme as opposed to trypanosome ornithine decarboxylase. Because mammalian ornithine decarboxylase is synthesized constantly at a high rate, DFMO must be continuously available, and this availability is made more difficult by rapid excretion.

DFMO has been used for melarsoprol-resistant *T. b. gambiense* infection with or without CNS involvement; treatment is started intravenously and is followed by oral therapy. In one study, 47 patients with a relapse after a first treatment were treated with a 7-day course of intravenous eflornithine 100 mg/kg every 6 hours and monitored for 2 years; the failure rate was 6.5 percent. This approach seems to provide adequate treatment in cases of Gambian trypanosomiasis relapsing after treatment with another drug. With adequate treatment, non-CNS disease has a cure rate greater than 80 percent. As previously noted, combination therapy with eflornithine and nifurtimox is a significant advance for therapy of *T. b. gambiense*.

Newer Therapeutic Agents

Available treatment regimens are limited, are associated with serious adverse effects, and are potentially compromised by the emergence of drug-resistant parasites. These considerations underscore the urgent need to develop inexpensive, safe, and efficacious new drugs.[90] It is hoped that efforts led by the Tropical Disease Research/World Health Organization Committee on Genomics and Discovery Research and the Drugs for Neglected Diseases Initiative will encourage further pharmaceutical efforts.[17]

Prophylaxis and Prevention

Chemoprophylaxis with suramin 0.3 to 0.7 g intravenously every 2 to 3 months is reported to be highly effective. With few exceptions, the vector has proved to be difficult to control. Preventing tsetse fly bites and chemoprophylaxis may be the best means of eliminating the disease from an area. Development of a vaccine has been hindered by antigenic variation.

At present, there are no endemic areas where *T. b. gambiense* and *T. b. rhodesiense* coexist. Although foci of both exist in Uganda, they apparently are geographically separate. Based on evidence of the spread of cattle carrying *T. b. rhodesiense* further north, a merger of the two foci could create tremendous problems because the diagnosis and treatment of the two diseases differ significantly.

Vector control measures have met with limited success. Methods have included clearing streams of underbrush, eliminating breeding grounds, using insecticides, using fly traps, and releasing sterile male flies. Because tsetse flies have a slow reproductive rate and have not developed insecticide resistance, *Glossina* spp. are tempting control targets. The most effective control measures include an integrated approach to reduce the human reservoir of infection and to use insecticides and fly traps.

In regions where the disease is endemic, natives seem to be more resistant to infection than new arrivals to the area, although there is no evidence of acquired immunity. West African sleeping sickness affects primarily rural populations, and tourists are rarely infected. Chemoprophylaxis is not recommended because of drug toxicity, and vaccines are unavailable. Despite antigenic variation, it may be possible to develop a vaccine because immunity to reinfection occurs with *T. b. gambiense*.

Tourists are usually not at great risk unless they are spending long periods in rural areas of western and central Africa.[86] Individuals visiting areas where the disease is endemic should avoid tsetse fly bites by wearing protective clothing (i.e., long-sleeved shirts and long pants); khaki or olive-colored clothing is optimal because the tsetse fly is attracted to bright colors and very dark colors. Because heavy clothing is not always practical owing to heat and humidity, other measures, including the use of insect repellents, bed netting, and screens, are recommended. It also has been recommended not to ride in the back of jeeps, pickup trucks, or other open vehicles; the tsetse fly is attracted to the dust created by moving vehicles and wild animals. Bushes should be avoided because the tsetse fly is less active during the hot period of the day and rests in bushes, but bites if disturbed.

CHAPTER 222

Naegleria, *Acanthamoeba*, and *Balamuthia* Infections

Patrick J. Gavin • Tina Q. Tan

Interest in free-living amebae has increased since demonstration of their pathogenicity and, more recently, their role as reservoirs and vectors for potentially pathogenic bacteria, such as *Legionella pneumophila* and *Mycobacterium avium*. Small free-living amebae of the genera *Naegleria*, *Acanthamoeba*, and *Balamuthia* cause severe central nervous system (CNS) infections in humans and animals that are characterized by few distinguishing symptoms and an almost uniformly poor prognosis. Although these severe infections are uncommon, for optimal treatment it is important to recognize and diagnose them early.

Although small free-living amebae share structural and pathogenic similarities, the infections they cause have distinctive epidemiology, clinical presentation and course, neuroimaging, immunology, and pathology. Primary amebic meningoencephalitis caused by *Naegleria fowleri* is an acute fulminant illness that affects healthy children and young adults and usually results in death within 1 week of presentation. Almost invariably, the patient has a recent history of swimming in bodies of warm fresh water, although there are recent reports of acquiring the infection through nasal irrigation using a neti pot. In contrast, granulomatous amebic encephalitis caused by *Acanthamoeba* spp. or *Balamuthia mandrillaris* (formerly leptomyxid amebae) is an insidious, subacute, and protracted illness that affects primarily, but not exclusively, immunocompromised or debilitated patients and leads to death in weeks to months. Typically, the patient has no history of recent exposure to fresh water. One other species of ameba belonging to the genus *Sappinia* has also been identified as a cause of encephalitis.[128]

Despite these differences, the prognosis of CNS infection caused by *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* is similarly dismal, with few reports of survival. In the handful of cases that survived from the hundreds reported, recognition, early diagnosis, and timely administration of appropriate antimicrobial treatment were crucial to achieving a successful outcome. *Acanthamoeba* spp. also are associated with disseminated cutaneous, pulmonary, or sinus infection in immunocompromised hosts and with chronic painful and potentially sight-threatening keratitis in association with use of contact lenses or corneal trauma in otherwise healthy patients.

The pathogenic potential of small free-living amebae was recognized first during polio vaccine trials in the 1950s, when they were found to cause cytotoxicity in contaminated cell cultures.[23,54] Subsequently, the fulminant fatal encephalitis that followed intracerebral injection or intranasal instillation of tissue culture fluid in experimental mice and monkeys showed pathogenicity and a potential route for human infection.[19,22,23] The first cases of human infection caused by small free-living amebae were recognized in four children from southern Australia by Fowler and Carter[36] in 1965 and soon afterward by Butt[12] in Florida.

More recently, Visvesvara and colleagues[130,131] isolated and named *B. mandrillaris*, a new agent of amebic meningoencephalitis, from the brain of a mandrill baboon. The first reported human case of *B. mandrillaris* encephalitis was in a patient with acquired immunodeficiency syndrome (AIDS).[3] Reports of infection in immunocompetent hosts have followed.[6,25,38,60,95] Subsequently, infections caused by free-living amebae have been reported worldwide.* Finally, the first case report of nonfatal CNS disease, in an otherwise healthy adult, caused by *Sappinia diploidea*, a free-living ameba normally found in soil contaminated with elk and buffalo dung, adds to the list of pathogenic small free-living amebae and suggests that others may be identified in the future.[41]

EPIDEMIOLOGY

Free-living amebae are found worldwide and are cosmopolitan in their distribution, living primarily in soil, but also in water, inside vertebrates, on plants, and in the air.[94] They are spread readily by wind and water currents. In humans, infection with free-living amebae causes primary amebic meningoencephalitis, granulomatous amebic meningoencephalitis, disseminated granulomatous disease (cutaneous, pulmonary, or sinus), and keratitis.[70,73,107]

Although they are rare, cases of infection caused by *N. fowleri* have been reported throughout the world.[35] As of 2004, more than 200 cases of primary amebic encephalitis were documented worldwide, with approximately half occurring in the United States.[20,107] In the United States between 1989 and 2000, 24 fatal cases of primary amebic meningoencephalitis were reported to the Centers for Disease Control and Prevention (CDC).[83] Most of them occurred in the summer and in young children. Increased water temperatures, whether from thermal pollution or sunlight, provide the ideal environment for proliferation of *N. fowleri*.[123,132] Cases typically are associated with a

*References 4, 61, 70, 73, 80, 97.

history of swimming, diving, or playing in bodies of warm fresh water, brackish habitats with a soil and water interface, artificial lakes, hot springs, and thermally polluted rivers and streams.* Researchers have postulated that thermal pollution, particularly from overflow of power plants, or inadequate chlorination of water kills off normal thermosensitive and chlorine-sensitive fauna, shifting the balance in favor of thermotolerant, less chlorine-sensitive, pathogenic *N. fowleri.*[107]

In North America, cases of primary amebic meningoencephalitis tend to be clustered in the warmer southern states and Mexico.[107] In one study, almost 50 percent of freshwater lakes in Florida contained *N. fowleri* when the temperature was 30°C or higher.[132] *N. fowleri* may be found in colder areas, however. In temperate regions, distribution of *N. fowleri* is limited by seasons, being greatest during summer and early fall.[123] *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* were present year-round in lakes in the Tulsa region of Oklahoma.[56] Although it is most prevalent in areas where water temperatures are higher, *N. fowleri* has the ability to overwinter, in cyst form, in sediment at the bottom of lakes.[132]

Small outbreaks of primary amebic meningoencephalitis have been described. Over a 3-year period, from 1962 to 1965, 16 swimmers died after being exposed to warm contaminated and inadequately chlorinated water in an indoor pool in Czechoslovakia.[16,107] Similarly, eight cases of fulminant meningoencephalitis associated with exposure to the water of an artificial lake in Richmond, Virginia, were recognized retrospectively as being caused by *N. fowleri.*[14] Finally, five cases of primary amebic meningoencephalitis caused by *N. fowleri* occurred in 1990 in patients swimming in a drainage canal in Mexicali, Mexico.[66]

Disease also has been documented in patients with no history of exposure to fresh water. Atypical exposures have included bathing in domestic bath water, playing in a warm muddy puddle, and being baptized by full-body immersion.[4,8,75] *N. fowleri* also has been shown in domestic tap water.[29,75] Although cases of infection have not followed ingestion of drinking water contaminated by amebae, fatal infection was associated with washing in tap water heated to high temperatures in pipes by the summer sun in South Australia and with exposure to contaminated domestic water in Arizona.[2,29,75]

Infections occur far more frequently in previously healthy children and young adults than in other age groups, presumably because youngsters are most likely to remain in water for prolonged periods and to disturb sediment containing amebae by diving and swimming underwater.[20,83] In one series of primary amebic meningoencephalitis cases, boys outnumbered girls 12 to 1, presumably because boys are more likely than girls to engage in aquatic horseplay.[129] The incubation period in natural human infection is 2 to 15 days after exposure.[8,20,83] Death usually ensues within 1 week of presentation (generally within 72 hours).

Acanthamoeba spp. are among the most prevalent protozoa found in the environment, being found in soils from tropical to arctic regions. They are important components of the food chain and promote plant growth by predation on soil bacteria. *Acanthamoeba* spp. are prevalent in natural and artificial habitats that include fresh, brackish, potable, or stagnant water; in sewage; in improperly treated swimming pools; and in taps, sinks, hot tubs, air-conditioning units, aquaria, flowerpots, showers, ventilators, and ventilation units in homes and hospitals.[17,33,73,105,107] Although warm waters might enhance their numbers, pathogenic amebae may be isolated year-round from water samples in the United States.[132] Their distribution and viability are governed primarily by availability of a bacterial food source; soil texture; water temperature, pH, and salinity and by ultraviolet light and desiccation.[94,107] Growth of *Acanthamoeba* spp. is inhibited by temperatures of 35°C to 39°C. Although *Acanthamoeba* spp. seemingly are ubiquitous in water, *Acanthamoeba* infections generally are not associated with a history of recent swimming or water activities.[107] Acquisition occurs by inhalation or direct contact with contaminated soil or water.

In contrast to *N. fowleri*, *Acanthamoeba* spp. are opportunistic pathogens. Granulomatous amebic encephalitis and disseminated disease caused by *Acanthamoeba* spp. generally are seen in immunocompromised hosts or in patients with underlying disease or debilitation, such as that due to malignancy, cancer chemotherapy, corticosteroid treatment, organ transplantation, human immunodeficiency virus, diabetes, or malnutrition.[70,73] *Acanthamoeba* spp. cause keratitis in otherwise healthy individuals by directly attacking the corneal surface, usually in association with poor contact lens care or corneal trauma. Although cases of CNS or disseminated *Acanthamoeba* infection are extremely rare, in 2004, estimates of cases of amebic keratitis worldwide exceeded 3000.[107]

Comparatively less is known about *B. mandrillaris.* It is closely related to *Acanthamoeba* and causes a similar spectrum of infections that includes granulomatous amebic encephalitis and cutaneous and sinus disease.[107] Although initial cases of *B. mandrillaris* infection were confined to immunocompromised and debilitated hosts, its ability to cause disease in apparently healthy children is well documented.[6,25,39,60,95] By 2004, more than 100 cases of human infection had been reported.[107] *Balamuthia* is assumed to inhabit soil and water; it has been isolated more recently in soil from a flowerpot associated with a case of amebic encephalitis in a child from northern California.[101]

As with *Acanthamoeba* spp., granulomatous encephalitis caused by *B. mandrillaris* seems to occur after inhalation of airborne cysts or soil contamination of breaks in the skin. The patient generally has no history of recent exposure to fresh water. To date, 50 percent of cases of *Balamuthia* infection reported in the United States have occurred in patients of Hispanic ethnicity.[6,103] Although this statistic most likely is a result of environmental exposure, a genetic predisposition may exist. Among California cases of balamuthiasis, most cluster in the southern part of the state. Researchers have postulated that the area's dry warm soil is conducive for the amebae and that large-scale agriculture in these areas increases the likelihood of workers being exposed to soil or wind-blown

*References 20, 26, 35, 71, 83, 123.

particles. Cases of *B. mandrillaris* infection linked directly to incidental exposure to soil or to blowing soil while traveling in an open car or by motorcycle are reported.[25,60,101,105] Although *Balamuthia* encephalitis is a zoonosis, animals do not represent a source of infection for humans.

Despite their seeming ubiquity in the environment and ample opportunity for contact with humans compared with other parasitic protozoa, such as *Entamoeba*, malaria and trypanosome infections caused by free-living amebae are extremely rare. Given the enormous number of exposures to water containing *Naegleria*, why so few individuals become infected remains unknown. Only seven cases of primary amebic meningoencephalitis were reported in Florida during a 14-year period, despite estimates of billions of potential exposures in contaminated freshwater lakes during that time period.[132] Epidemiologic investigations of cases typically find that many other individuals swam in the same water at the same time but did not become ill. Factors other than the presence of amebae, such as host susceptibility, anatomy, inoculum size, and activity at the time of exposure, have been implicated.[132] Nonetheless, in recent years, an increase in the number of diagnoses of primary amebic meningoencephalitis cases has been noted.[68,137] The increase probably reflects a combination of greater recognition of the pathogenic potential of free-living amebae, improved diagnostic techniques, and a growth in the numbers of immunocompromised hosts.

Acanthamoeba organisms can infect the cornea directly, after trauma, or, most commonly, in association with the combination of extended-wear soft contact lens use and subsequent exposure to contaminated water.[109,118] Major risk factors for development of amebic keratitis include poor compliance with care of daily wear soft contact lenses, particularly use of homemade saline solutions using nonsterile tap water that may be contaminated with amebae; use of chlorine release lens disinfection systems; and inadequate cleansing of lens cases, which encourages growth of a bacterial biofilm that acts as a nidus and a food source for amebae.[91,117] Wearing contact lenses while swimming or in hot tubs, which potentially may be contaminated with amebae, is similarly risky.[96]

Since the first cases of amebic keratitis were described in the early 1970s, the incidence has increased dramatically. Between 1973 and 1984, slightly more than 200 cases of amebic keratitis were reported to the CDC. By 2002, in the United States, more than 3000 cases had been reported and 1 in 250,000 people were estimated to be affected.[58,65,85,107] The increased incidence most likely is due to increased use of contact lenses, particularly of the soft, extended-wear variety. Although many of these lenses were marketed as products requiring "low care," many patients interpreted this designation as meaning "no care."[91]

ORGANISMS

In contrast to the related true parasite protozoa *Entamoeba* spp., *Naegleria*, *Acanthamoeba*, and *Balamuthia* spp. are amphizoic protozoa, capable of existing as free-living amebae and as parasitic pathogens.[107] *Naegleria* spp. are ameboflagellates found primarily in moist soil and warm fresh water.[71] Although more than 27 separate *Naegleria* spp. have been identified, to date only *N. fowleri* is associated with human infections.[26,107] *Naegleria* spp. can exist in three forms: an active feeding trophozoite, a rarely seen dormant cyst (Fig. 222-1), and a flagellate form (Fig. 222-2).[71] Of these forms, only the trophozoite is found in tissue or cerebrospinal fluid (CSF). The trophozoite of *N. fowleri* is smaller than that of *Acanthamoeba* spp., measuring 8 to 15 μm in diameter, with a conspicuous nucleus containing a large, dense central karyosome without peripheral chromatin lining the membrane.[79] *Naegleria* trophozoites move slowly by extension of broad, rounded anterior pseudopodia (lobopodia). This feature may be noted on a warm saline preparation or in CSF specimens. *Naegleria* cysts are spherical, measure 7 to 12 μm in diameter, and have a single-layered outer membrane.

Approximately 20 *Acanthamoeba* spp. are identified by morphologic criteria.[107] Because morphologic distinctions do not always correlate with results of molecular typing, however, classification is complex and is currently

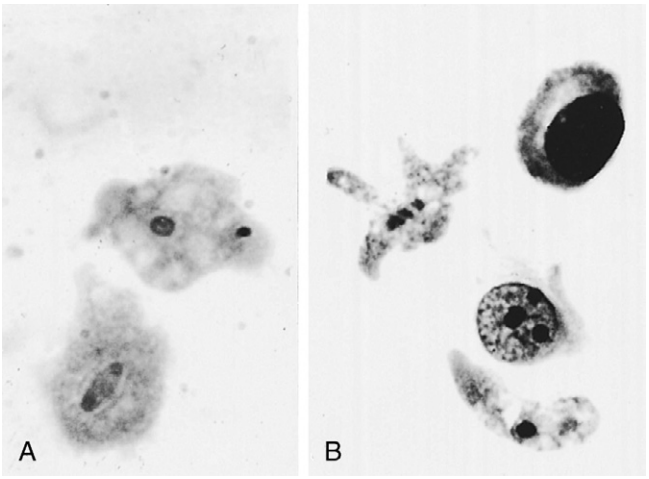

FIGURE 222-1 ■ **A** and **B,** Trophozoites of *Naegleria.*

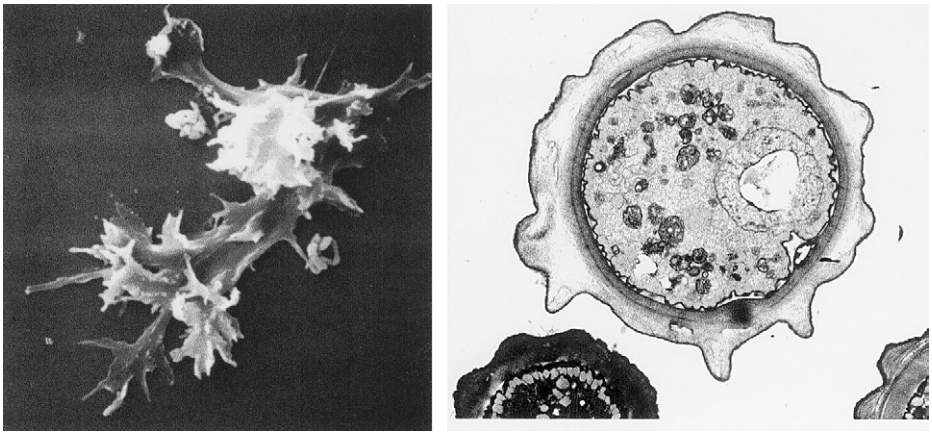

FIGURE 222-4 ■ Trophozoite and cyst of *Balamuthia mandrillaris*. (Courtesy Dr. G. S. Visvesvara, Centers for Disease Control and Prevention.)

under review.[73] Molecular classification is ongoing. The life cycle of *Acanthamoeba* spp. consists of two stages: an actively feeding and dividing trophozoite and a dormant cyst stage (Fig. 222-3).[87] The trophozoite is 15 to 40 µm. The nucleus is vesicular; has a large, dense central "targetoid" nucleolus; and is surrounded by vacuolated cytoplasm. Locomotion typically is sluggish, by extrusion of multiple fine spiny pseudopodia (acanthopodia).[79] *Acanthamoeba* trophozoites feed on bacteria, yeasts, and algae. *Acanthamoeba* cysts are smaller, 15 to 20 µm, with a distinct, wrinkled, thick double wall. Encystation occurs in response to adverse environmental conditions, such as desiccation, scarcity of food, and changes in pH or temperature. *Acanthamoeba* cysts are particularly hardy; they are intrinsically resistant to chlorination and sterilization of potable water, to biocides used for disinfecting bronchoscopes and contact lenses, and to antibiotics; they may remain viable for decades after freezing.[27,63,81] *Acanthamoeba* is the only pathogenic free-living species isolated from marine water. *Naegleria* spp. do not tolerate sea water.

Few *Acanthamoeba* spp. have been associated with human infections. Among the potentially pathogenic species, *Acanthamoeba culbertsoni*, *Acanthamoeba castellanii*, *Acanthamoeba astronyxis*, and *Acanthamoeba polyphaga* are prominent.[80] On the basis of 18S rRNA gene sequences *Acanthamoeba* spp. are divided into 15 genotypes (T1 through T15). At present, no clear consensus has been reached regarding which genotypes are pathogenic. Genotypes T1, T4, T7, T10, and T12 are found among cases of granulomatous encephalitis, whereas isolates associated with keratitis fall into genotypes T3, T4, and T11.[10,34,73,120] Genotype T4 makes up 94 percent and 80 percent of keratitis and nonkeratitis *Acanthamoeba* isolates, respectively,[10] presumably reflecting the preponderance of this genotype in the environment. Rare genotypes, such as T1, T10, and T12, are found only in CNS disease and are not found in the environment.

B. mandrillaris is the only pathogenic *Balamuthia* spp. identified to date.[107] It exists as either a vegetative trophozoite or a dormant cyst (Fig. 222-4). Trophozoites are similar in appearance to *Acanthamoeba* spp. but larger (50 to 60 µm in diameter), and the spherical cyst stage (10 to 30 µm in diameter) has a triple-layered wall on electron microscopy. *Balamuthia* trophozoites typically have a single vesicular nucleus, often with multiple large, dense nucleoli. Movement occurs by extension of broad pseudopodia. *Balamuthia* has been isolated more recently from environmental soil samples.[31] Because of its slow growth, it may have been obscured in environmental

cultures by overgrowth of more rapidly growing bacteria, fungi, or other amebae. In contrast to *Naegleria* and *Acanthamoeba* spp., *Balamuthia* feeds on smaller amebae and protozoa and does not prey on bacteria.

S. diploidea is a species of free-living amebae that is found worldwide. The life cycle of this organism involves animal feces. The trophozoites are 40 to 70 μm in diameter and can be distinguished by the presence of a large cytoplasmic vacuole, mitochondria with characteristic tubular crystal patterns, a juxtanuclear Golgi-like network, and a double nucleus.[41]

CLINICAL MANIFESTATIONS

Naegleria fowleri

Primary amebic meningoencephalitis caused by *N. fowleri* is an acute, rapidly progressive illness that almost uniformly is fatal. Patients have an abrupt onset of severe headache, fever, nausea and vomiting, malaise, rhinitis, meningitis, and changes in mental status 1 to 15 days after exposure (typically 5 to 8 days), most frequently after swimming or bathing in warm contaminated fresh water.[35,70,83,111] A history of disturbances of taste and smell has been noted in many cases, although for the most part the early clinical features of primary amebic meningoencephalitis are not distinctive.[49] Progression from fever to signs of meningitis and encephalitis is unrelenting and rapid. Seizures are common. Coma is present at or develops soon after hospital admission. In the absence of early diagnosis and appropriate treatment, the illness characteristically progresses rapidly to death within 1 week of onset of symptoms (median, 72 hours).[8]

Other than the clue of a recent history of exposure to warm water, there is little to distinguish primary amebic meningoencephalitis from fulminant bacterial meningitis. A high peripheral polymorphonuclear leukocytosis may be present. CSF findings are similarly nonspecific, with increased pressure, elevated protein level, a normal to low glucose value, and modest polymorphonuclear pleocytosis, but no bacteria, mycobacteria, or fungi are identified. Patients with a suggestive history and CSF indices suggestive of purulent meningitis, but without bacteria on Gram stain, should have a wet mount examined for the presence of motile trophozoites (Fig. 222-5).

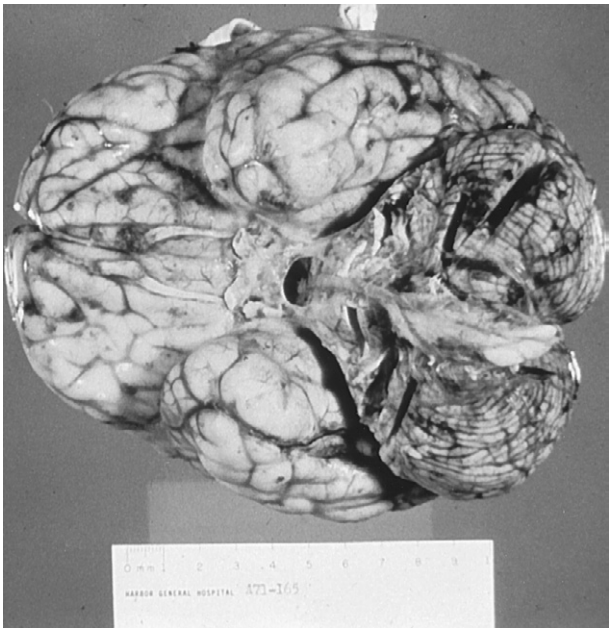

FIGURE 222-5 ■ Brain from a fatal case of *Naegleria* meningoencephalitis. Note the areas of necrosis on the basilar surface of the brain.

Acanthamoeba Species

Acanthamoeba spp. and *B. mandrillaris* cause granulomatous amebic encephalitis. The course typically is prolonged, with progression from focal neurologic signs to diffuse meningoencephalitis over weeks to months after exposure.[73,107] Patients most susceptible to contracting this disease include very young, old, debilitated, immunosuppressed, and chronically ill patients. The clinical picture resembles that of a bacterial brain abscess or brain tumor, with insidious headache, intermittent low-grade fever, nausea, vomiting, and symptoms of increased intracranial pressure. Altered mental status is particularly prominent. As the infection progresses, depending on the area of the brain affected, focal neurologic signs, hemiparesis, drowsiness, aphasia, behavioral and personality changes, and seizures develop. The incubation period after exposure to onset of CNS disease is unknown but is of the order of several weeks to months.

Acanthamoeba skin lesions often have been present for months before the onset of CNS disease. Routine CSF findings frequently are abnormal but nonspecific, with elevated protein level, low glucose value, and, typically, a mononuclear pleocytosis. *Acanthamoeba* spp. also may cause cutaneous, pulmonary, bone, and nasopharyngeal or sinus disease.[42,69,77] Cutaneous *Acanthamoeba* infection is characterized by pustules and hard erythematous nodules, which develop into nonhealing indurated draining ulcers or subcutaneous abscesses.[37,73] Disseminated disease without CNS involvement has a slightly better prognosis. In patients with AIDS, mortality rates of 70 percent and 100 percent are reported for *Acanthamoeba* skin disease alone and in association with CNS disease, respectively.[59]

Acanthamoeba Keratitis

In contrast to its role as an opportunistic pathogen in CNS and skin disease, most cases of *Acanthamoeba* keratitis occur in otherwise healthy individuals who wear contact lenses or who have a history of corneal trauma. Contact lenses of any type, including daily wear and disposable soft and extended-wear lenses, have been implicated in infection. All soft contact lenses contain 50 to 75 percent water. These lenses can absorb pathogens from contaminated cleaning solutions, carrying cases, and hands. When the lens comes into contact with the contaminated fluid, the amebae quickly adhere to the lens surface. If corneal trauma is present, the organisms invade the corneal tissue and produce infection.[57] The nidus for

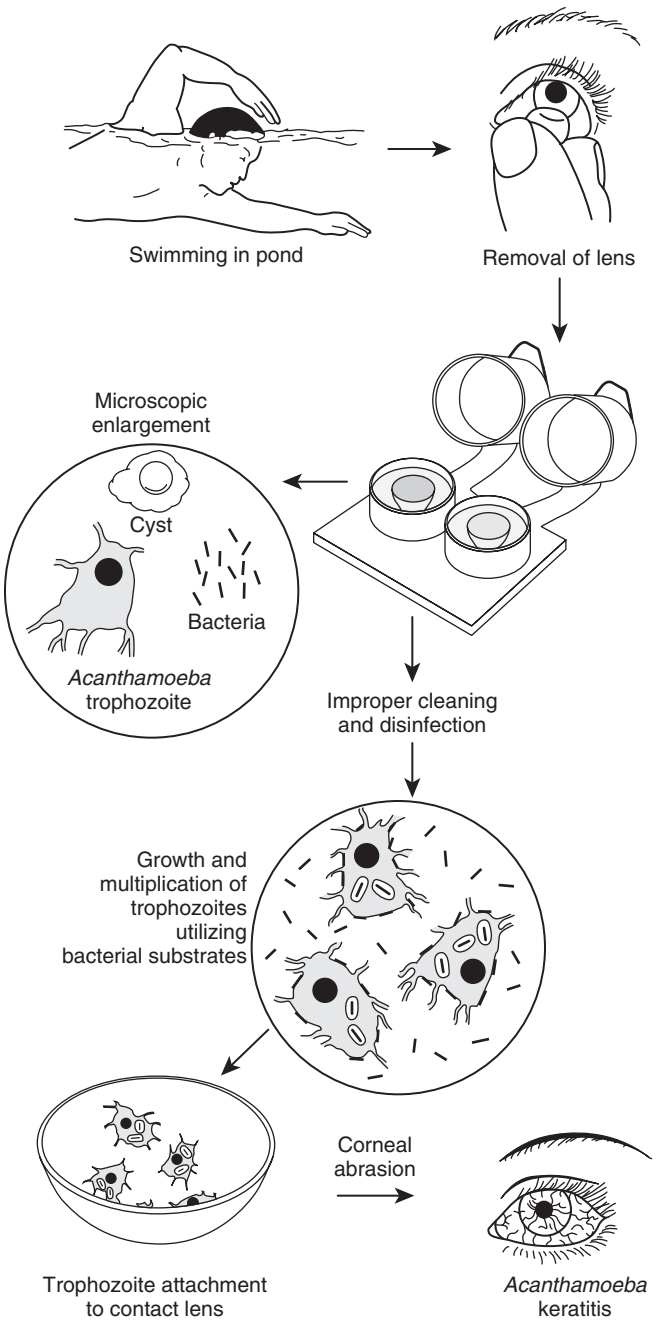

FIGURE 222-6 ■ Proposed mechanism for *Acanthamoeba* keratitis. Bacterial contaminants in the water on the lens support the growth of amoebae, which leads to an increased number of invading organisms. The organisms adhere to the contact lens and enter tissue through the damaged cornea, with the subsequent development of keratitis.

infection most likely is trauma to the cornea but also may be related to preexisting herpesviral or bacterial conjunctivitis (Fig. 222-6).

Amebic keratitis characteristically is painful, progressive, and sight threatening and fails to respond to conventional antibacterial or antiviral treatment.[5,73] Typically, only one eye is involved. Early symptoms include severe eye pain, lacrimation, foreign body sensation, and photophobia. *Acanthamoeba* keratitis frequently is misdiagnosed, initially, as herpetic, bacterial, or fungal infection. The course usually is more indolent, however. Periods of temporary remission delay establishing the diagnosis further. Recurrent corneal epithelial breakdown with dendritic infiltrates progresses to nonsuppurative keratitis, which waxes and wanes over several months and ends in a characteristic ring-shaped stromal abscess with secondary uveitis leading to loss of the cornea.[5,125] Infection that follows severe trauma deteriorates more rapidly than that which follows contact lens wear. In addition, complications of infection include iritis, cataracts, hypopyon, glaucoma, scleritis, and penetrating keratitis.[5]

Balamuthia mandrillaris

B. mandrillaris causes granulomatous encephalitis and cutaneous, sinus, and nasopharyngeal disease.[107] The incubation period of CNS disease is unknown but is thought to be weeks to months (not <10 days).[80] In animal models, extensive CNS necrosis develops 1 to 3 weeks after inoculation.[78] Onset of symptoms of granulomatous encephalitis is insidious, with low-grade fever, severe frontal headache, nausea and vomiting, meningismus, personality change, and prominent focal neurologic signs that have included cranial nerve palsies, hemiparesis, dysarthria/aphasia, focal seizures, and ataxia.[6,47] A history of recent otitis was noted by many authors.[6,47] A slow relentless deterioration to coma and death ensues over several weeks to months (as long as 2 years afterward). Death usually results from cardiorespiratory failure secondary to severe cerebral edema. In many reports, manifestation of cutaneous lesions (facial, nasal, and limb) has preceded development of CNS disease.[25,53,89,92,133] Although normal CSF parameters have been described in *B. mandrillaris* CNS infection, moderately increased protein levels (may be >1 g/dL), normal or mildly decreased glucose values, and a pleocytosis (about 500 cells/mm^3), which commonly but not invariably has a mononuclear predominance, are the typical findings.[6,39,47,78,107]

NEUROIMAGING

Neuroimaging findings in infections caused by free-living amebae are nonspecific and alone do not provide clues to an earlier diagnosis. In addition, in the early stages of infection, results of computed tomography (CT) and magnetic resonance imaging (MRI) may be normal. In primary amebic meningoencephalitis, cranial CT and MRI show obliteration of basal cisterns and signs of diffuse brain edema, focal and basilar meningeal enhancement, and infarction.[64,98,112] In granulomatous encephalitis, neuroimaging reveals variable but nondiagnostic abnormalities that include, alone or in combination, discrete corticomedullary lesions; large, solitary, masslike lesions (which may be confused with brain abscess or tumor); large arterial occlusions; and spinal cord infarctions.[64,98,112] Similarly, in *Balamuthia* infection, neuroimaging is helpful but nondiagnostic; CT scans show a focal enhancing mass or ring-enhancing cystic lesions or both, vascular occlusion, and diffuse edema that frequently progresses to communicating hydrocephalus.[6,25,47]

PATHOGENESIS

Naegleria trophozoites or cysts enter the nasal cavity by aspiration of water or inhalation of soil. After active phagocytosis by sustentacular neuroepithelial cells of the olfactory nerve occurs, trophozoites migrate along the nerve, pass through the cribriform plate, and gain entry to the CNS.[55,80] From the olfactory bulb, which is bathed in CSF and lies in the highly vascularized subarachnoid space, *N. fowleri* disseminate throughout the CSF and CNS. Only *Naegleria* trophozoites are found in the CNS lesions. In contrast, most *Acanthamoeba* spp. infections seem to follow hematogenous dissemination from a primary lower respiratory or cutaneous focus.[80] Researchers have postulated that *Acanthamoeba* spp. are inhaled or inoculated through skin in the cyst phase. Less commonly, *Acanthamoeba* is capable of causing CNS infection directly via the olfactory neuroepithelium.

Virulence factors described for free-living amebae include the ability to adhere to brain microvascular epithelium, production of extracellular protease and elastases, and phagocytosis by food-cups or amebostomes.* Among *Naegleria* spp., pathogenicity is closely related to thermotolerance.[26] *N. fowleri*, the only species pathogenic for humans, is unusually thermophilic and can tolerate temperatures of 45°C.[107] In addition, *N. fowleri* has less demanding growth requirements than nonpathogenic *Naegleria* spp. Trophozoites of pathogenic *Acanthamoeba* spp. also are thermophilic, being able to tolerate temperatures of 37°C, relative to their nonpathogenic counterparts.[99,107] Thermotolerance seems to be less important for *Acanthamoeba* strains that cause keratitis, presumably because corneal temperatures are lower (32°C to 35°C).[107]

PATHOLOGY

Pathologic changes of infection with small free-living amebae are most marked in the CNS. The pathology of primary and granulomatous amebic encephalitis differs fundamentally.[80] Macroscopically, *N. fowleri* produces diffuse meningoencephalitis, most severely affecting the cortical gray matter. It is characterized by marked cerebral edema and purulent leptomeninges, particularly adjacent to the olfactory bulbs, at the base of the frontal and temporal lobes, and at the hypothalamus.[79] Frequently, the olfactory bulbs are necrotic and hemorrhagic. Microscopically, an acute mononuclear and polymorphonuclear inflammatory infiltrate is seen throughout the cerebrum, brain stem, and cerebellum and the upper spinal cord. Trophozoites tend to concentrate in the perivascular spaces and adventitia of arteries, and they may contain ingested erythrocytes and brain tissue. Characteristically, only trophozoites are seen in the CSF or brain tissue.[80] Presumably, *N. fowleri* cysts are not found in clinical specimens because progression of *Naegleria* infection is so rapid and fatal that the patient dies before transformation from trophozoite into the cyst can occur.[70]

CNS infections caused by *Acanthamoeba* spp. and *B. mandrillaris* are characterized macroscopically by diffuse cerebral edema and hemorrhage, with areas of softening and abscess formation. The meninges are spared except for areas overlying involved cerebrum. Additional areas of hemorrhagic necrosis are concentrated in the posterior fossa, brain stem, cerebellum, midbrain, cerebral cortex, and basal ganglia.[6,25,28,70] Narrowing of the sulci and flattening of the gyri are noted in areas of active infection. Microscopic changes consist of multinucleated giant cells, with trophozoites and cysts seen within the lesions.[79] The olfactory bulbs and spinal cord are relatively spared.

Microscopically, necrotizing hemorrhagic encephalitis and subacute or chronic necrotizing granulomatous infiltrates and multinucleate giant cells are scattered throughout the CNS, particularly in the cerebral hemispheres, basal ganglia, midbrain, and brain stem. Typically, trophozoites and cysts of *Acanthamoeba* spp. or *B. mandrillaris* are present within necrotic cerebral tissue, particularly in perivascular spaces. Invasion of blood vessels causes severe necrotizing arteritis and hemorrhagic necrosis. The angiotropic distribution of *Acanthamoeba* or *Balamuthia* infection supports a hematogenous mechanism of spread. In severely immunocompromised patients, the inflammatory reaction may be negligible and lacks a granulomatous component.[9,78] In the absence of a vigorous granulomatous response, hemorrhagic necrosis that resembles primary amebic meningoencephalitis may occur.[134]

Skin lesions of acanthamebiasis and balamuthiasis are characterized by nodules, ulcers, and abscesses and by the presence of amebic trophozoites, cysts, and granulomas in tissue.[77,80,133] Amebic keratitis is characterized by moderate chronic inflammation of corneal stroma, a mixed polymorphonuclear and lymphocytic infiltrate, and the presence of amebic trophozoites and cysts within the corneal ulcerations.[129]

DIAGNOSIS

Previously, most cases of amebic meningoencephalitis were diagnosed with certainty only at autopsy or by brain biopsy.[9] Routine laboratory tests did not distinguish amebic meningoencephalitis from other causes of meningoencephalitis. The first and most important diagnostic step is to recognize the possibility that small free-living amebae may cause infection in the appropriate clinical setting. Among the few reported therapeutic successes, all are notable for early diagnosis and timely institution of appropriate antimicrobial therapy.[25,88]

Primary amebic meningoencephalitis should be included in the differential diagnosis of any child or young adult with meningoencephalitis. A history of recent exposure to fresh water should be sought, and a wet mount should be performed on centrifuged CSF. *Naegleria* is isolated most readily from CSF but also may be isolated from brain tissue, particularly olfactory lobes. In contrast, *Acanthamoeba* trophozoites characteristically are absent from CSF and *B. mandrillaris* has yet to be seen

*References 1, 33, 48, 62, 71, 73.

in CSF. *Acanthamoeba* spp. are more likely to be isolated from brain tissue or skin biopsy or from corneal scrapings in cases of keratitis.[99] Diagnostic techniques include direct microscopy of wet-mount and stained CSF specimens, histologic stains of tissue, fluorescent and immunofluorescent antibody stains of CSF and tissue, direct immunohistochemical stains of tissue, serology, molecular diagnostics, and culture.[127]

Direct Microscopic Identification

If amebic infection of the CNS is suspected, a wet-mount preparation of fresh CSF should be examined for the presence of motile amebae.[70,79,80,127] This method remains the most rapid means of diagnosis. Ideally, the CSF specimen should be kept at room temperature and examined soon after it has been collected. *Naegleria* is particularly fragile. Although the specimen may be kept at 4°C for short periods, it never should be frozen.[127] If present, amebae tend to attach to the test tube wall or surface of the container, so gentle shaking and low centrifugation at 150 *g* for 5 minutes is recommended to dislodge and concentrate the amebae.[79,127] The supernatant should be placed gently on a slide. The wet mount is examined best by light microscopy under low power (10× and 40× objectives), phase-contrast microscopy, or darkfield illumination and may be warmed to promote amebic motility. *Naegleria* trophozoites move in a characteristic "sluglike" fashion by extrusion of a few broad pseudopodia (lobopodia) anteriorly.[107] Leftover specimens can be frozen at –20°C for later antigen or antibody testing. Although *N. fowleri* may be shown by histologic stains of fixed CSF smears, Gram stain is not useful because it does not stain amebae and the heat fixation causes lysis.

Naegleria, *Acanthamoeba* spp., and *Balamuthia* may be shown in fixed sections of brain tissue biopsy or autopsy specimens by hematoxylin and eosin, Masson trichrome, periodic acid–Schiff, Wright-Giemsa stain, and Gomori–methenamine silver stains (Fig. 222-7).[70,73,79,80] Reliably differentiating *Acanthamoeba* and *Balamuthia* by histology alone is difficult. In addition, *Acanthamoeba* trophozoites have been variously mistaken for macrophages or "atypical mononuclear" or epithelial cells on routine histology.[79,134]

Immunofluorescent stains using monoclonal and polyclonal anti-*Acanthamoeba* and anti–*B. mandrillaris* antibodies (available at the CDC), immunoperoxidase staining, and electron microscopy of tissue sections have been used to confirm the diagnosis (Fig. 222-8).[25,59,72,127,128] Amebic keratitis may be diagnosed by direct detection of trophozoites or cysts in smears of deep corneal scraping or biopsy using Wright-Giemsa, trichrome, periodic acid–Schiff, calcofluor white, or indirect fluorescent antibody stains.[70,79,135]

Culture

Culture has a limited role in diagnosis but is useful for confirmation, speciation, and antimicrobial susceptibility testing. *N. fowleri* and *Acanthamoeba* spp. can be cultivated using bacteria as a food source (xenic cultures) or without bacteria, in an enriched cell-free nutrient (axenic) medium that contains antimicrobial agents to inhibit growth of contaminating bacteria.[21,99,110,127] *N. fowleri* and *Acanthamoeba* spp. are readily cultured from CSF, brain, and lung tissue on various non-nutrient agars or with low concentrations of nutrients, in the presence of a lawn of living or killed bacteria (e.g., most commonly nonmucoid strains of *Escherichia coli* or *Enterobacter* spp.).[79,99,127] Amebae feed on the lawn of bacteria and grow to cover the plate after 1 to 2 days' incubation at 37°C. Culture plates are incubated at 37°C and examined under low power daily for 10 days.[79,127]

Amebae can be visualized directly through the back of the inverted agar plate with a conventional microscope under low power.[99] The characteristic slow, sluglike movement of *Naegleria* trophozoites that is readily seen in a wet mount of CSF is difficult to distinguish on an agar plate.[99] The ability of *Naegleria* to transform into the

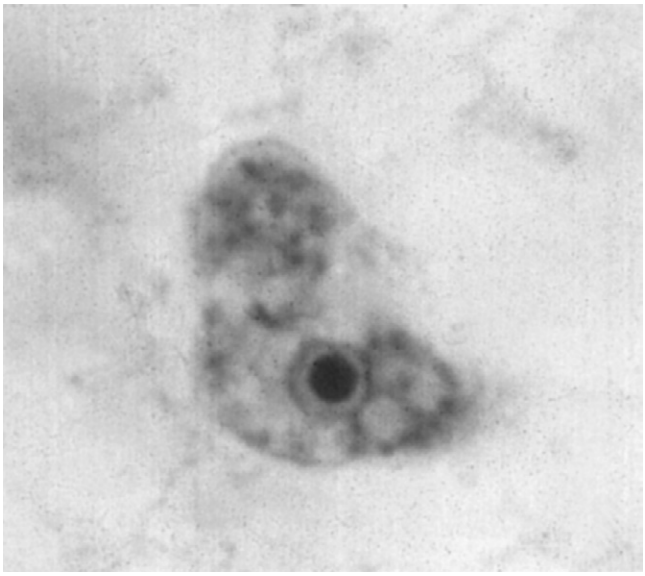

FIGURE 222-7 ■ Trichrome stain of a trophozoite of *Naegleria fowleri.*

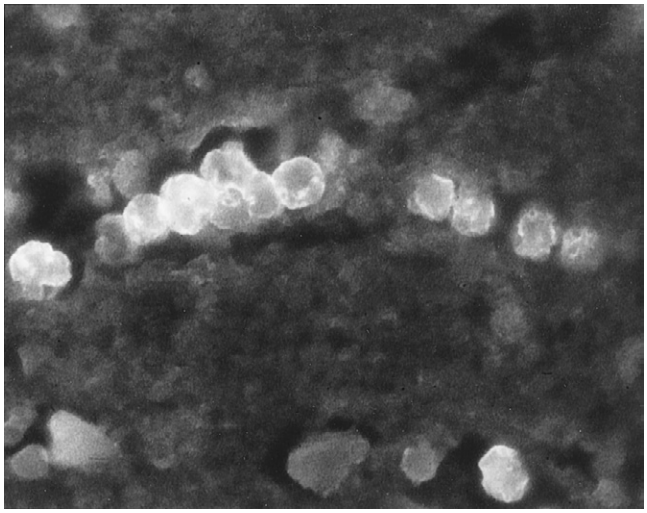

FIGURE 222-8 ■ Indirect fluorescent antibody examination of *Naegleria fowleri.* (Courtesy Dr. G. S. Visvesvara, Centers for Disease Control and Prevention.)

flagellated stage after suspension in distilled water is useful diagnostically.[99,127] Trophozoites of *Acanthamoeba* spp. move slowly by extrusion of multiple, finger-like pseudopodia (acanthopodia).

Culture and isolation of *Balamuthia* is more challenging. Generally, *B. mandrillaris* is more fastidious, does not use bacteria as a food source, grows slowly, and requires a heavily enriched basic medium. *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* all grow vigorously, however, and produce detectable cytopathic effects in mammalian cell cultures (monkey kidney, HeLa, and lung fibroblast tissue), which can be examined for cytopathic effect.[79,130] Typically, *Balamuthia* grows slowly and may require several weeks to proliferate.[130] Use of a positive control culture is advised to ensure correct methodology and to aid recognition.[99]

Although no outbreaks of infection caused by free-living amebae in laboratory workers have been reported, care must be taken when handling specimens to avoid getting culture materials on skin and in cuts or abrasions. Specimens should be handled in a biologic safety cabinet by technologists wearing masks and gloves.[79,127]

Serology

Although specific *N. fowleri* antibody has been shown in survivors of primary encephalitis, serologic tests are of no use diagnostically.[111] Onset of primary amebic meningoencephalitis is rapid, and almost all patients die before significant antibody production can occur. In contrast, because the clinical courses of *Acanthamoeba* spp. and *B. mandrillaris* infections usually are chronic, robust antibody responses have time to develop. Detection of serum or CSF antibody against *Acanthamoeba* spp. or *Balamuthia* by indirect immunofluorescence staining has helped establish the diagnosis in many cases.[25,60,107,124] By this method, amebae fixed on a slide bind antibody present in the patient's serum or CSF, which then is detected by fluorescein-conjugated, antihuman antibody.

Serologic testing has been most useful as an epidemiologic tool. Although the incidence of infection with free-living amebae seems low, results of seroepidemiology studies suggest that human exposure to amebae occurs frequently. Sera from healthy adults and children contain antibody against *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris.*[24,51,74,102,105] Detection of antibodies to *N. fowleri* and *Acanthamoeba* spp. in asymptomatic adult and pediatric populations from North Carolina, Virginia, and Pennsylvania in the United States and from Czechoslovakia and New Zealand presumably reflects unavoidable environmental contact with these ubiquitous organisms.[15,74] All specimens from a group of 93 asymptomatic patients from New Zealand contained anti-*Naegleria* and anti-*Acanthamoeba* IgG and IgM antibodies.[24] Antibodies were neutralizing against *Acanthamoeba* spp. but not against *N. fowleri.* In virtually all cases of infection caused by *Acanthamoeba* spp., disease occurs in the setting of immunocompromise or in an immunologically privileged site, such as the cornea. Whether neutralizing antibodies play a role in the very low incidence of infections in healthy individuals, despite seemingly frequent environmental exposure, is unknown.

Immunofluorescent antibody staining of serum for antibodies against *Acanthamoeba* spp. and *B. mandrillaris* has proved to be a rapid noninvasive diagnostic test in many clinical cases.[29,60,135] Potentially, this test may be useful clinically for establishing an earlier definitive diagnosis and initiation of therapy. Because the presence of *Balamuthia* antibodies may represent asymptomatic environmental exposure, confirmation of results of immunofluorescent antibody testing by histology, indirect immunofluorescent staining of tissue, or polymerase chain reaction (PCR) of CSF is advised. More recently, immunofluorescent antibody staining of serum from patients with encephalitis, predominantly from California, revealed seven previously unrecognized or misdiagnosed cases of *Balamuthia* and one case of *Acanthamoeba* encephalitis.[105] Most serum specimens showed some evidence of antibody (<1 : 64), which was attributed to cross-reactivity or subclinical exposure to contaminated soil. A cutoff value of greater than 1 : 64 for *Balamuthia* serology was considered positive pending results of confirmatory tests (e.g., histology, immunohistochemistry, or PCR).[105] Low levels of antibody may reflect preceding subacute disease or contact with environmental amebae.[105]

Molecular Diagnostics

Although microscopic assessment of a wet-mount preparation or histology may be useful in experienced hands, definitive identification in most centers awaits results of specimens sent out for immunofluorescence tests. Advances in molecular diagnostics offer the real possibility, however, of sensitive, specific, and rapid diagnosis being made by any laboratory with the capability to perform PCR. PCR of DNA extracted from frozen brain tissue has been used to confirm *N. fowleri* infection diagnosed by histopathology and immunofluorescent staining.[20] Similarly, nested and real-time PCR provide rapid, sensitive, and specific screening of environmental and recreational water sources for the presence of *N. fowleri.*[75,93] PCR, using mitochondrial 16S rRNA gene DNA as the target, has been used to detect *B. mandrillaris* in clinical samples of CSF and formalin-fixed brain and lung tissue of patients with encephalitis.[119,136] These assays have the ability to detect a single ameba per reaction mixture.[136]

Finally, the development of a multiplex real-time PCR assay for simultaneous detection of *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* in clinical specimens of CSF and brain tissue offers the possibility of highly sensitive and specific rapid confirmatory diagnosis of CNS infection by free-living ameba and the chance of initiating earlier, more effective treatment.[90] The assay is sensitive down to detection of a single ameba in a specimen and is species specific for *N. fowleri* and *B. mandrillaris* and genus specific for *Acanthamoeba.*[90]

TREATMENT

Mortality among patients with primary and granulomatous amebic encephalitis is greater than 95 percent.[8,108] Indeed, there are only a handful of known survivors of

primary amebic meningoencephalitis.[49] The high fatality rate undoubtedly is due partly to late diagnosis or misdiagnosis and late initiation of potentially effective treatment. Inclusion of amebic infection in the differential diagnosis, in the appropriate clinical setting, and timely administration of effective antiamebic treatment are emphasized in successful cases.[11,88] In the future, availability of real-time PCR may facilitate accurately establishing an early diagnosis. Although no randomized trials of optimal treatment for infection caused by free-living amebae have been performed, potentially effective treatment is available if the condition is recognized early.

If infection is suspected, treatment should not be withheld pending the results of confirmatory testing. Treatment regimens are based on results of in vitro susceptibility, in vivo animal experiments, and empirical treatment of individual cases. If amebic infection is suspected, accurate determination of the species is important to ensure optimal treatment. No one drug is effective against all free-living amebae (e.g., amphotericin is the drug of choice for *N. fowleri* infection but is neither amebistatic nor amebicidal for *Acanthamoeba* spp. and varies in its efficacy against *Balamuthia*).[30,106] Previously, authors have suggested initiating treatment with a combination of agents such as amphotericin B and flucytosine, which have activity against *Naegleria* and *Acanthamoeba* or *Balamuthia*, until amebae can be identified definitively.[134] Among newer antibiotics, miltefosine and voriconazole are potentially attractive as treatments for infection caused by free-living amebae. Both drugs penetrate into brain tissue and have a low toxicity profile. Although differences in susceptibility exist among strains, voriconazole has activity in vitro against *Acanthamoeba* spp. and *N. fowleri*, whereas miltefosine has in vitro activity against *Acanthamoeba* spp. and *Balamuthia*.[104]

Amebic Meningoencephalitis

N. fowleri is exquisitely susceptible in vitro to amphotericin B, which remains the treatment of choice for primary amebic meningoencephalitis.[108] All successfully treated cases have included amphotericin B in the treatment regimen. *Naegleria* also is susceptible in vitro to azithromycin and miconazole, with synergism in vitro and in the animal model with the combination of amphotericin and miconazole or tetracycline.[30,43,111,115,126] Treatment regimens in cases with successful outcomes have included intravenous amphotericin, high-dose intravenous and intrathecal amphotericin and miconazole, oral rifampin, intravenous sulfisoxazole, and intravenous and intrathecal amphotericin in combination with oral rifampin.[4,11,111] In at least one reported case, intravenous and intrathecal amphotericin B was combined with intravenous and intrathecal miconazole and with oral rifampin.[49] Rifampin has yielded conflicting results in in vitro testing.[44] Liposomal amphotericin B seems less effective in vitro and in the animal model than conventional amphotericin (10-fold higher minimum inhibitory concentration) and is not recommended.[44] Promising results in mice have been reported with chlorpromazine and to a lesser extent miltefosine and voriconazole.[128] In contrast to *Acanthamoeba* spp. and *B. mandrillaris*, *N. fowleri* remains a trophozoite and does not encyst in tissues, so after it is destroyed by antimicrobial therapy, infection with *N. fowleri* should not recur.

Optimal treatment for CNS disease caused by *Acanthamoeba* spp. has not been established, and the prognosis remains grim, with few reports of survivors.[108] Most cases are diagnosed at autopsy or a few days before death, leaving little time to evaluate treatment. Treatment successes have been attributed to initiation of treatment before spread of infection into the CNS. Combination treatment is favored because no single drug is active against trophozoites and cysts, and many drugs are amebistatic rather than amebicidal.[73] Among the few reports of successful treatment, orally administered trimethoprim-sulfamethoxazole, ketoconazole, and rifampin were associated with a favorable outcome in two apparently immunocompetent children with CNS disease.[113] Fluconazole, rifampin, metronidazole, and sulfadiazine were used successfully in a 64-year-old immunocompetent host with early disease.[88] Still other regimens have included pentamidine isethionate, 5-fluorocytosine, and itraconazole.[128]

Similarly, Slater and colleagues[114] reported successful treatment of disseminated cutaneous acanthamebiasis in a renal transplant recipient using 4 weeks of intravenous pentamidine, topical chlorhexidine, and 2 percent ketoconazole followed by maintenance oral itraconazole. A combination of pentamidine, 5-fluorocytosine, itraconazole, and topical chlorhexidine gluconate/ketoconazole cream was used to treat disseminated acanthamebiasis successfully in a lung transplant recipient.[86] Pentamidine is considered the most suitable treatment before CNS invasion has occurred because of its low penetration into the CNS. Because of its low penetration across the blood-brain barrier and nephrotoxicity, 5-fluorocytosine was preferred to pentamidine for CNS infection and in renal transplant recipients.[30,73] The anti-*Leishmania* drug miltefosine has been found to be useful both for systemic infections and amebic keratitis.[128]

Optimal treatment for *B. mandrillaris* infection also remains to be determined. Reports of successful treatment for granulomatous encephalitis caused by *Balamuthia* based on empirical regimens are few. If it is recognized early in its course, however, a more favorable outcome apparently is possible. According to Visvesvara, in the 100 cases reported only seven patients have survived, including four patients treated with a combination of flucytosine, pentamidine isethionate, fluconazole, sulfadiazine, and a macrolide such as azithromycin switched to clarithromycin (better CSF penetration), whereas some patients also received a phenothiazine (thioridazine or trifluoperazine).[25,128] Pentamidine treatment frequently was discontinued or interrupted because of side effects. Treatment failures have been reported in patients treated with similar regimens, however, possibly because of late initiation of treatment.[39] Pentamidine and azithromycin were more effective in vitro than fluconazole, flucytosine, or sulfasalazine.[108] Some researchers have postulated, however, that some of these drugs may be synergistic in vivo.[108] Because of concern about reactivation from dormant cysts in the brain, both patients remained on long-term fluconazole and on sulfadiazine

or clarithromycin prophylaxis. The drug miltefosine has also been used. One patient underwent excision of a brain abscess while undergoing treatment.

Use of corticosteroids to treat cerebral edema and inflammation seems to exacerbate *Acanthamoeba* infection. A precipitous decline in the clinical condition of one patient has been reported after administration of corticosteroid therapy.[39] At present, the risk of corticosteroid treatment probably outweighs any potential benefit and is best avoided.[39,73,95]

Amebic Keratitis

If untreated, amebic keratitis invariably progresses to visual loss and enucleation. Although amebic keratitis is more amenable to antimicrobial treatment than systemic infection, treating it is still difficult. The presence of *Acanthamoeba* cysts in deeper corneal layers renders exposure to adequate drug levels problematic. In addition, *Acanthamoeba* cysts are resistant to most antibacterial agents at concentrations that are achievable but nontoxic to the cornea. As with systemic infection, establishing the diagnosis early is required for treatment to be most effective.

In the early stages of infection, prolonged frequent application of drug is recommended. Combination treatment is preferred during prolonged treatment because of concerns for development of resistance. Nonetheless, cures have been reported with a variety of topical agents; the cationic antiseptic chlorhexidine gluconate and 0.02 percent polyhexamethylene biguanide (PHMB), a swimming pool disinfectant, alone or in combination with propamidine are among the drugs of choice for amebic keratitis.[32,67,108,109] Both drugs are effective against trophozoites and are well tolerated in the eye.[67] Alternatively, two diamidines, propamidine isethionate and hexamidine, can be used or chlorhexidine can be used along with diamidine.[128] Visvesvara reports that they should be used hourly as drops day and night for 48 hours initially, followed by hourly drops by day only for another 72 hours and, then, because of epithelial toxicity, tapered to 2 hours by day 5 for 3 to 4 weeks. Neomycin and oral azoles (e.g., miconazole or itraconazole) also have proved useful. Newer agents, such as myristamidopropyl dimethylamine and miltefosine, are effective *Acanthamoeba* cysticidal agents, possess excellent antifungal and antibacterial activity, and show promise in treating recalcitrant keratitis.[52,100,108]

Many cases of keratitis, particularly when chronic or where medical treatment alone fails, require keratoplasty and corneal grafting. In these cases, prolonged medical treatment aims to cure or control disease to allow for successful transplantation. Timing of surgery is controversial. Antiamebic drugs usually are continued for months after surgery to prevent late excystation of residual dormant cysts.[5] Use of topical or systemic corticosteroid to treat severe pain or inflammation is controversial. Severe complications have been described in clinical cases, and dexamethasone induces encystment and increases cytopathogenicity of emerging trophozoites in animal models.[82,120]

Role of *Acanthamoeba* Species as Reservoirs of Intracellular Pathogens

Although most bacteria are prey for free-living amebae, some bacteria have evolved to survive uptake by amebae. Many *Acanthamoeba* spp. act as environmental reservoirs of recognized intracellular pathogens for humans, including *Coxiella burnetii*, *Legionella pneumophila*, *Mycobacterium* spp., *Pseudomonas aeruginosa*, and *Cryptococcus neoformans*, and for potential emerging pathogens, such as *Rickettsia*-like organisms and *Parachlamydia* spp.[45,46,50,76,122] Some ameba-resistant microorganisms coexist with amebae as endobacterial symbionts, whereas others exploit the amebae as hosts for survival, for multiplication, or as vectors of disease.[7] Free-living amebae act as a "Trojan horse" in the transmission of bacterial passengers, such as for *L. pneumophila* or *M. avium*, or as an "evolutionary crib" for the selection of virulence traits and for adaptation of microorganisms to life within human macrophages, such as for *C. neoformans*.[7,46]

For *L. pneumophila*, prior multiplication within free-living amebae, principally *Acanthamoeba* spp., seems to be a prerequisite for acquisition of infection in humans.[121] In addition, many bacteria, such as *M. avium*, survive protected from chlorination, biocides, antibiotics, and desiccation within ameba cysts.[72,119] Similarly, growth of *M. avium* in amebae results in enhanced survival in macrophages. Researchers also have postulated that free-living amebae may have adapted some microorganisms for successful intracellular survival within macrophages.[40,116] Free-living amebae also apparently promote virulence traits and antimicrobial resistance in *L. pneumophila*, *M. avium*, and *C. neoformans*.[18,19,84] Researchers have postulated that capsule formation evolved in *C. neoformans* in response to selective pressure to resist environmental amebae. Production and maintenance of a capsule allows *Cryptococcus* to survive in human macrophages.[116] Some microorganisms resistant to amebae seem to behave as endosymbionts and to influence development and maintenance of virulence traits that enhance pathogenicity of free-living amebae.[38,46] Clinical and environmental *Naegleria* spp. do not support bacterial endosymbionts.

PREVENTION

Infections caused by free-living amebae are reported to be characterized by an absence of distinguishing symptoms, delayed diagnosis or misdiagnosis, and an almost uniformly poor prognosis without early appropriate treatment. Prevention of infection is of paramount importance. Strategies to prevent *Naegleria* infection exist; *N. fowleri* is susceptible to 1 μg/mL or less of chlorine, and adequate chlorination of water in swimming pools or hot tubs is a simple and sensible preventive measure. If water temperatures are higher, use of increased concentrations of chlorine (>2 to 3 mg/L) is recommended.[80] In certain parts of the world, environmental levels of *N. fowleri* are monitored to ensure it is safe to swim and that the probability of acquiring an infection is

low.[13] A prudent measure is to educate the public on the potential dangers associated with exposure to warm bodies of fresh or thermally polluted water, especially when temperatures are high and water levels are low, and to avoid immersion, diving, jumping, or horseplay that might force water up the nasal passages or disturb sediment.[137] If a neti pot is used for nasal irrigation, only bottled or filtered water should be used.

Prevention of infection caused by *Acanthamoeba* spp. or *B. mandrillaris* is problematic and involves regular inspections of hot-water tanks, plumbing, and eye-wash stations. *Acanthamoeba* keratitis associated with use of contact lenses is preventable, however. Contact lens wearers should be aware of the importance of proper care of the lenses. Lenses should be cleansed in sterile benzalkonium-preserved saline or disinfected by heat. Use of homemade cleansing solutions and wearing lenses while swimming are contraindicated.

Although the incidence of infections caused by free-living amebae is small at present, the number of these infections is likely to grow with increasing numbers of transplant patients and patients with AIDS. Similarly, some researchers have predicted that climate change associated with global warming may increase further the numbers of free-living amebae in the environment.[20]

CHAPTER 223

Toxoplasmosis

James B. McAuley • Kenneth M. Boyer • Jack S. Remington • Rima L. McLeod

Toxoplasma gondii is an obligate intracellular protozoan parasite (phylum Apicomplexa, class Sporozoasida, order Eucoccidiida).[214] Infection may be clinically inapparent or result in disease, called toxoplasmosis. This parasite was observed first in 1908 by Nicolle and Manceaux[159,160,196] in mononuclear cells in the spleen and liver of a North African rodent, the gundi *(Ctenodactylus gundi)*. The organism soon was identified as a cause of disease in other animals,[209] and in 1923, Janku[96] first recognized a case in a human. He described a parasite found in the retina of an infant; it was recognized later by Levaditi[121] as *Toxoplasma*.

In 1937, Wolf and Cowen[222] reported a case of congenital granulomatous encephalitis that they considered to be caused by an "encephalitozoon." Sabin,[185] who previously had encountered *T. gondii* in guinea pigs, made the correct diagnosis. The discovery of *Toxoplasma* as a cause of disease acquired later in life has been credited to Pinkerton and Weinman,[166] who in 1940 described a generalized fatal illness caused by this organism in a young man. In retrospect, a case of acquired toxoplasmosis had been reported in 1908 by Darling.[47] In 1948, Sabin and Feldman[186] described a serologic test, the dye test that allowed numerous investigators to study the epidemiologic and clinical aspects of toxoplasmosis and to define the spectrum of disease in humans. In 1969, some 60 years after the parasite was discovered, Frenkel and colleagues[60,69,70] established that *Toxoplasma* is a coccidian protozoan and that its definitive host is the cat.

ORGANISM AND TRANSMISSION

T. gondii exists in three forms or stages: the proliferative stage, or tachyzoite; a tissue cyst that contains bradyzoites; and an oocyst, within which sporozoites develop. The oocyst is formed during the intestinal epithelial stage of infection, exclusively in members of the cat family, the definitive host. The tachyzoite and tissue cyst are found in the extraintestinal tissues of cats and in other mammalian and avian hosts. Each stage of the organism has antigens in common with the other stages and unique antigens. Many of these antigens have been cloned, sequenced, and localized to microanatomic structures.[144] Humans may become infected from any of the three forms as detailed later.

The tachyzoite form (Fig. 223-1A-C) is crescent shaped or oval, is approximately 3 by 7 μm, and is seen

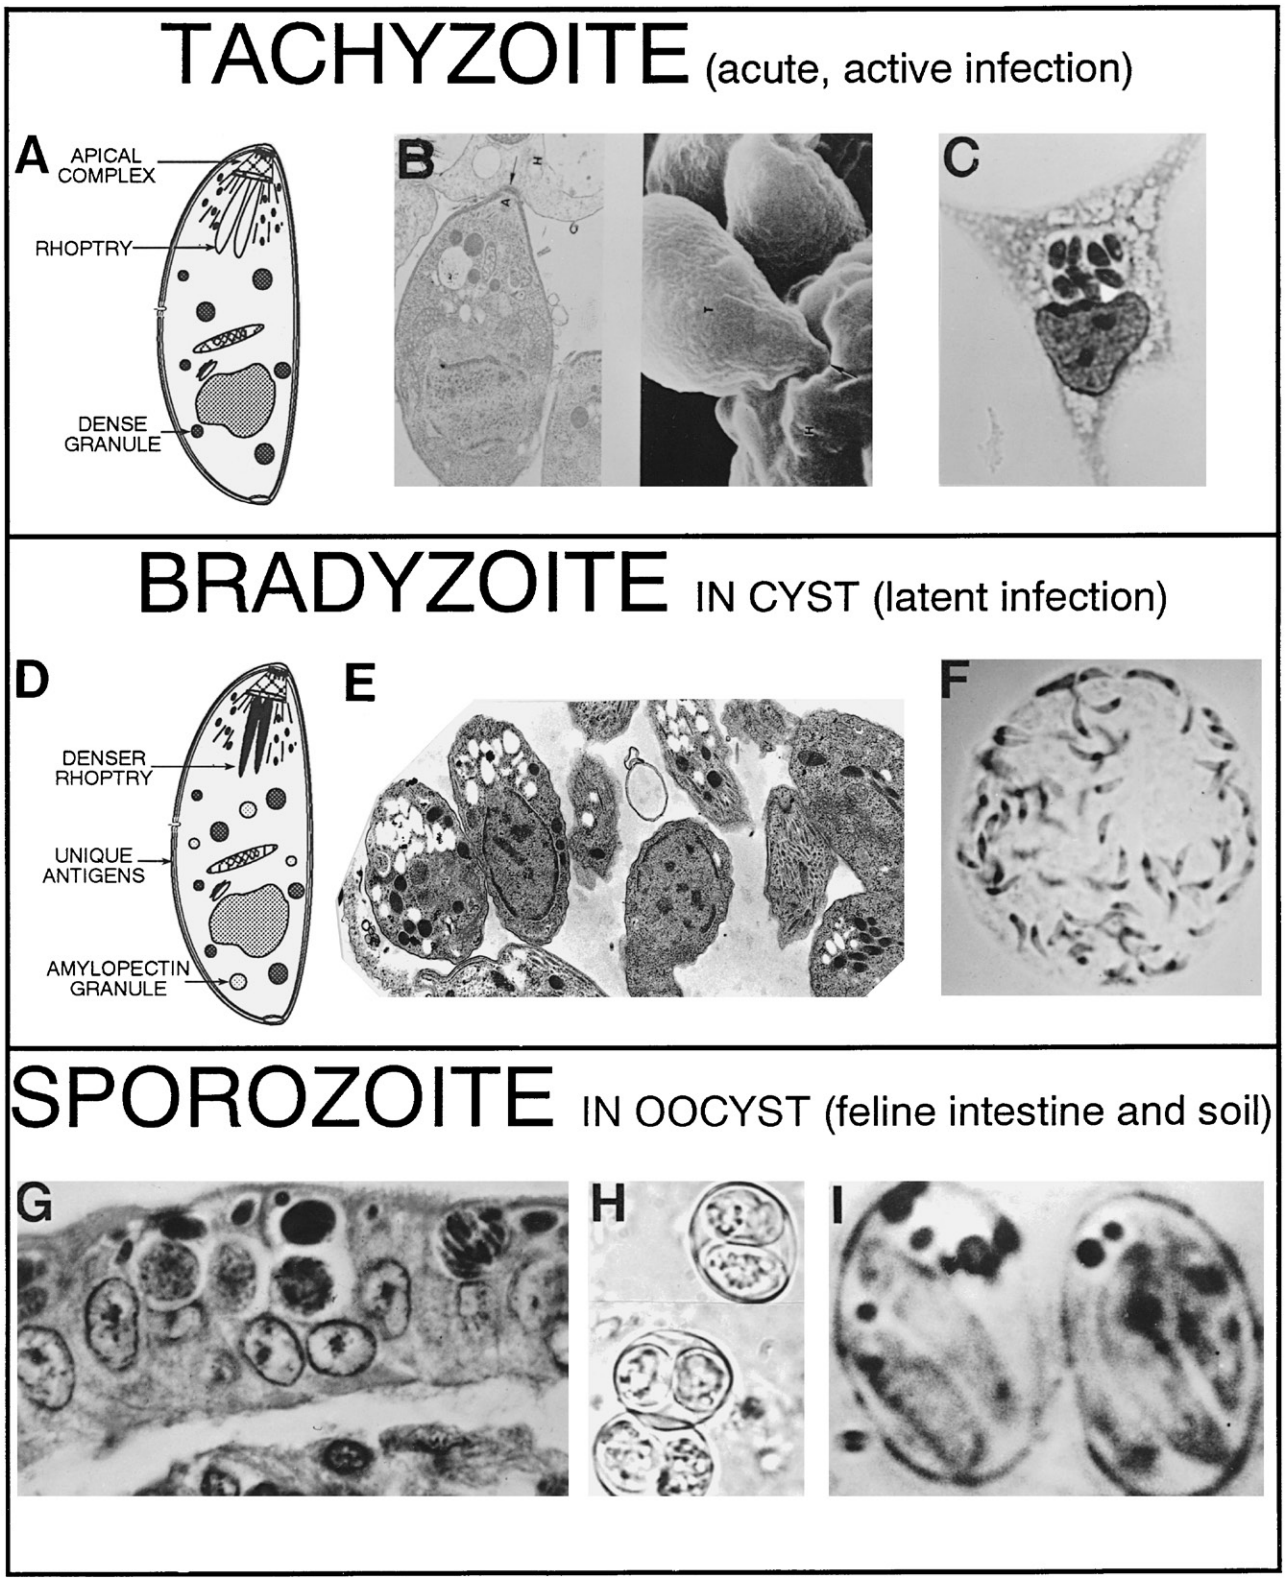

FIGURE 223-1 ■ Stages of *Toxoplasma gondii*. **A,** Schematic diagram of a tachyzoite. **B,** Transmission and scanning electron micrographs of a tachyzoite invading a host cell. **C,** Light micrograph of tachyzoites replicating within a parasitiferous vacuole in the host cell cytoplasm. **D,** Schematic diagram of a bradyzoite. **E,** Transmission electron micrograph of a cyst containing bradyzoites (*arrow* indicates amylopectin granules). **F,** Light micrograph of a cyst containing bradyzoites. **G,** Development of oocysts in cat intestine. **H,** Oocysts in the lumen of cat intestine. **I,** Sporulating oocysts that contain sporozoites. (From Boyer KM, McLeod RL. *Toxoplasma gondii* [toxoplasmosis]. In: Long SS, Pickering LK, Prober CG, editors. *Principles and practice of pediatric infectious diseases*. New York: Churchill Livingstone; 1997, p. 1423.)

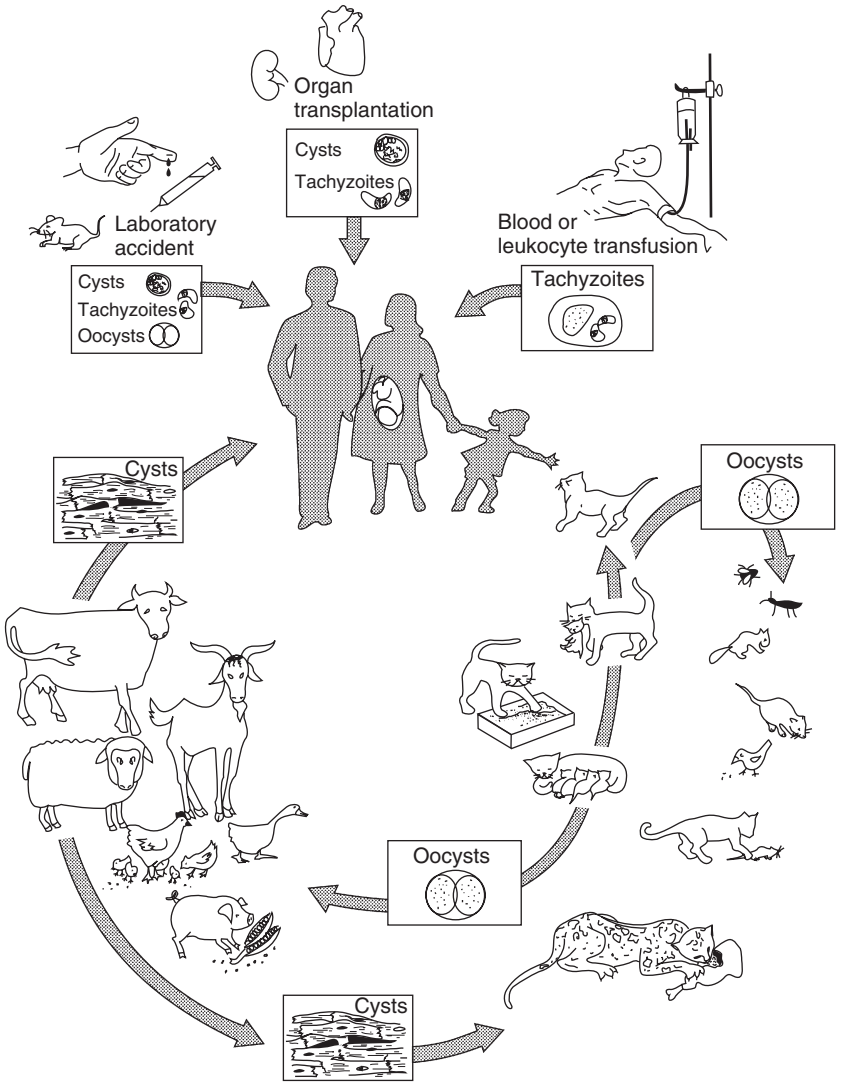

FIGURE 223-2 ■ Life cycle of *Toxoplasma gondii*. Cats are definitive hosts, with humans and other mammals being intermediate hosts. (From Remington JS, McLeod R. Toxoplasmosis. In: Braude AI, editor. *International textbook of medicine. Medical microbiology and infectious disease.* vol. II. Philadelphia: Saunders; 1981, p. 1818.)

during the acute stage of infection. It stains well with Wright or Giemsa stain. Ultrastructural features include the apical complex of microtubules and rings, secretory organelles called rhoptries, and a chloroplast-like structure with its own unique DNA.[31,61,214] Tachyzoites can invade all mammalian cells except perhaps non-nucleated red blood cells. They cannot withstand freezing and thawing, desiccation, or brief exposure to gastric or duodenal digestive juices. After penetration occurs, the tachyzoite multiplies by endodyogeny, ultimately causing disruption of the cell and cell death.

The bradyzoite (Fig. 223-1D-F) is able to persist in encysted form in all tissues and cause a chronic (latent) infection for the entire lifespan of the infected host. Cysts are demonstrable in tissues the first week of infection and range in size from approximately 10 to 100 μm. They have an argyrophilic wall but stand out most clearly from surrounding tissue when stained with periodic acid–Schiff stain. Usually, no inflammatory reaction occurs around cysts. Because this form may persist for many years in the tissues of clinically normal children and adults, its demonstration in histologic sections does not signify recent infection. Peptic or tryptic digestive fluids immediately disrupt the cyst wall, but the liberated bradyzoites (which resemble the tachyzoite form under light microscopy) can survive in these fluids for several hours, which allows time for invasion of local cells. The cyst is destroyed by heating to 66°C (150°F), by freezing (below –20°C [–4°F]) and thawing, and by desiccation. It can survive for some months at refrigeration temperatures (4°C [39°F]) if it is in tissue. Infection in humans may be acquired by eating inadequately cooked meat that contains cysts (Fig. 223-2). In carnivorous animals, infection may be acquired by eating raw meat or prey species that contain encysted organisms or by ingesting sporulated oocysts as discussed subsequently.

The oocyst form (Fig. 223-1G-I) is found only in feces of members of the cat family, the definitive host for *Toxoplasma*, and is the result of gametogony and schizogony, which occur in the intestinal epithelium.[71,94] The oocyst is ovoid and approximately 10 to 12 μm. Infected cats may shed 10 million oocysts each day, which may be excreted for 3 weeks after primary (acute) infection develops but rarely thereafter. Excreted oocysts become

infectious only after they undergo sporulation (eight sporozoites form in each oocyst); sporulation occurs 1 to 21 days (most commonly 2 to 8 days) after excretion, depending on temperature and the availability of oxygen. The oocyst is far more resilient than the other life cycle forms and can survive for months in water and for 1 year or more in moist soil. Ingestion of sporulated oocysts transmits the infection. This fact suggests that the oocyst plays a major role in transmission by the fecal-oral route in animal reservoirs and by inadvertent ingestion in humans.

The genome of *T. gondii* consists of 8×10^7 base pairs distributed among 12 chromosomes. Much of the genome has been sequenced, a genetic linkage map has been constructed, and three clonal genotypes (I, II, and III) have been identified.[46,111,193,214] Some of the factors that regulate stage conversion from tachyzoite to bradyzoite have been defined.[144,214] The shikimate pathway, an enzyme system that is absent in animals, is important for the production of many essential aromatic compounds in plants, bacteria, and fungi. This biochemical pathway has been identified in *Toxoplasma* and in other apicomplexan parasites, such as *Plasmodium falciparum* and *Cryptosporidium parvum*.[178] Biochemical inhibition of this pathway suppresses the growth of these parasites.[175] Understanding of the regulation of life cycle stages and the unique pathways of intermediary metabolism in *T. gondii* may provide new approaches to therapy.

EPIDEMIOLOGY

Acquired Infection

The cat is central in the parasite's life cycle, and humans and other mammals are intermediate hosts. If infected tissue (e.g., a mouse) is consumed by a susceptible cat, the sexual cycle is induced in the cat intestine; oocysts are excreted and are infectious for mammals and birds, in which the life cycle (tachyzoites and cysts) is perpetuated. Cats shed oocysts for only brief durations (days to weeks) but in extremely large numbers (1×10^7/day). A cat is more likely to become infected if it is an outdoor cat or a predator or is fed fresh, uncooked table scraps. Humans come in contact with cat excrement either directly (e.g., emptying the litter pan) or by more insidious means (e.g., cleaning a horse stall, weeding the garden, playing in a sandbox). Meat for human consumption containing tissue cysts may serve as a source of infection if it is eaten raw or undercooked. Accidental ingestion may occur under circumstances that are unsuspected. In a recent report, only 49 percent of women with acute primary toxoplasmosis during pregnancy who gave birth to infected children could identify significant risk factors for sporozoite acquisition.[18] Examples of inadvertent exposures include an Amish farm wife preparing sausage, a couple consuming steak tartare in an expensive restaurant, and a rancher butchering a deer.[19] Mode of infection probably varies geographically according to cultural dietary and soil exposure practices. In Chile, 43 percent of women with recent infection had antibody to sporozoite-specific protein (oocysts), suggesting ingestion of undercooked infected meat as the main mode of acquisition.[155]

Infection with *Toxoplasma* occurs commonly in humans. In the United States, the prevalence of seropositivity has been determined from studies of military recruits, from surveys in major cities, and most comprehensively from the National Health and Nutrition Examination Surveys (NHANES). The NHANES are periodic cluster sample surveys representing the entire population of the United States. In the early 1960s, the overall prevalence in military recruits was 14 percent, with the lowest rates in the Mountain (3%) and Pacific (8%) states and the highest rates in the Northeast (20%) and East South Central (19%) states.[194] A more recent study from the late 1980s showed a similar geographic distribution, but prevalence rates were approximately a third lower throughout the country.[194] This decline has continued as documented in the NHANES.

NHANES III (1988-1994) showed an overall seroprevalence in individuals of child-bearing age (12 to 49 years old) of 14.1 percent compared with a rate of 9 percent for the same age cohort in the 1999-2004 NHANES.[101] The consistent gradual increase in seropositivity with increasing age in the surveys suggests dietary exposure as a major mode of acquisition in the United States.[102] Previous estimates were that approximately 8 percent of commercial beef, 20 percent of commercial pork, and 25 percent of commercial lamb contain encysted *Toxoplasma* bradyzoites.[172] More recent data suggest much lower levels of viable tissue cysts in commercial meat.[59] The NHANES III failed to show an association, however, with specific dietary habits such as meat consumption. *Toxoplasma* infection was associated with foreign birth, low educational level, living in crowded conditions, and having a soil-related occupation.[102]

During these decades of declining prevalence of *Toxoplasma* infection, the rate of cat ownership has increased in the United States.[101,102] The decline may be explained partly by improved meat safety, with decreasing prevalence of viable *Toxoplasma* in commercial meat.[59] A common practice is to freeze commercial meat before releasing it for sale, which, combined with the use of home freezers, also may be having a beneficial effect.[193] However, recent trends toward free-range organically raised meat could increase the risk of *T. gondii* contamination of meat.[99] Additional modes of transmission, such as waterborne,[11,16,58] have been described. Their exact contribution to the overall prevalence of toxoplasmosis in the United States is unclear, however. During the decades of the NHANES studies, an increasing proportion of U.S. water supplies have added filtration to decrease *Giardia* and *Cryptosporidium* transmission. This filtration also is likely to eliminate *Toxoplasma* oocysts.[102]

Urban studies in U.S. women of child-bearing age have yielded variable prevalence rates: Denver, 3 percent; Palo Alto, 10 percent; Chicago, 12 percent; Boston, 14 percent; and Birmingham, 30 percent.[172] Internationally, rates also vary: Japan, 6 percent; Australia, 23 percent; United Kingdom, 35 percent; Poland, 36 percent; Belgium, 53 percent; Tahiti, 77 percent; and France, 87 percent.[172] The prevalence of infection is determined partly by climate; colder regions and regions that are hot and dry or at high altitude have lower rates of human infection than warmer and moister regions do.

Prevalences are declining in Europe, as in the United States, owing to educational efforts and improved meat safety.

Despite declining prevalence in the United States, it is estimated that more than 1 million new infections occur each year with resultant ocular lesions in more than 21,500 persons, of which approximately 4800 are symptomatic.[100] The rate of hospitalization for human immunodeficiency virus (HIV)–associated toxoplasmosis has declined since the advent of effective antiretroviral therapy; however, hospitalization for non–HIV-associated toxoplasmosis has remained steady from 1993 to 2008.[103]

Common-source outbreaks of acute acquired *Toxoplasma* infection have been authenticated. Unique and clear-cut sources that have been documented to be highly likely[16] include exposure to aerosolized cat excrement in a riding stable[204] and consumption of unpasteurized goat milk.[187] In other circumstances, extensive investigations have failed to yield convincing answers.[130,191] Because of the possibility of common-source exposure, however, families of patients with acute acquired infection should be evaluated for subclinical infection.[127] In 2012, the Centers for Disease Control and Prevention included an exercise in foodborne toxoplasmosis on a college campus in its tabletop training for emerging infectious disease threats.[154]

Accidental self-inoculation with a needle contaminated with *Toxoplasma* has resulted in many acquired infections in laboratory workers. Infections also have been ascribed to blood transfusions and organ transplantation.[68]

Congenital Infection

Infection of the fetus occurs during maternal parasitemia, with subsequent infection of the placenta caused by tachyzoites.[70,172] Placental infection represents an important intermediary step between maternal and fetal infection. A delay of 16 weeks between placental infection and subsequent infection of the fetus has been noted and is termed the prenatal incubation period.[172] Congenital infection is thought to occur, with rare exception, only after primary maternal infection with *Toxoplasma*.[52,172] The only two well-documented exceptions to this rule occurred in immunodeficient pregnant women.[148,172] Maternal reinfection leading to congenital toxoplasmosis also has been reported very rarely.[75,172] In a large series that carefully studied more than 800 women who had given birth to congenitally infected children, not a single congenital infection occurred in subsequent pregnancies.[172] A general consensus is that only acute infection beginning *during* pregnancy can lead to congenital infection. Despite the existence of a few well-documented cases of biopsy-proven lymphadenopathic toxoplasmosis occurring 2 months *before* conception that resulted in congenitally infected infants,[209] this pattern of occurrence also seems to be extremely rare.[75] Congenital toxoplasmosis has occurred in twins and triplets, with occasional discordance.[37,172]

The incidence of congenital toxoplasmosis in a population is determined by the risk of a woman's experiencing primary infection while she is pregnant. This incidence depends on three factors: (1) the age-specific incidence of primary infection during the child-bearing years, (2) the age distribution of pregnant women in the population, and (3) the fetal transmission rate in primary infection. A theoretical analysis by Frenkel[69] based on these three factors, assuming a child-bearing age group of 20 to 29 years and an overall fetal transmission rate of 40 percent, showed that maximal risk occurs when the age-specific incidence rate in a population is 3 to 5 percent per year, which corresponds to a seropositivity rate of 50 to 80 percent in women of child-bearing age. In such a population, the predicted prevalence of congenital toxoplasmosis would be 4.4 to 4.6 per 1000 pregnancies. At higher age-specific incidences, rates of congenital toxoplasmosis would be lower because nearly all pregnant women already would be infected chronically. At lower incidences, rates also would be lower but because of less frequent infection.

Studies in the early 1970s revealed an incidence of congenital toxoplasmosis in the United States of approximately 2 per 1000 births.[1,12,112,172] More recently the incidence of congenital infection in the United States has been documented to be 0.08 per 1000 births (1 in 12,000 births) by IgM screening of blood specimens collected on filter paper from newborns in Massachusetts and New Hampshire.[87] This is a conservative estimate as the methodology detects approximately 75 percent of infections. The figure compares with a rate of 3 to 10 per 1000 live births in Paris and Vienna. In Massachusetts, a case-control study involving 14 years of newborn screening for congenital toxoplasmosis found that birth of the mother outside the United States, particularly in Cambodia and Laos, and the educational level and higher gravidity of the mother were strongly predictive of congenital infection.[97]

PATHOLOGY

After intracellular multiplication at the site of entry occurs, tachyzoites are disseminated in blood and may invade all organs and tissues. The severity of infection probably is a function of strain virulence, host susceptibility, tissue tropism, and the immune privilege of the eyes and central nervous system (CNS).[84,85,129,172] Proliferation of tachyzoites results in death of the invaded cells and, eventually, small necrotic foci surrounded by intense cellular reaction. With recovery, cysts without an inflammatory response around them may persist in the brain, retinas, bone marrow, lymph nodes, liver, spleen, and lungs and in skeletal, heart, and smooth muscle.[68-70]

In active infection of the CNS, *Toxoplasma*-filled cells are scattered throughout the gray matter, where they produce diffuse meningoencephalitis with miliary microglial nodules and foci of perivascular inflammation.[35] Large lesions may mimic cerebral tumors. Areas of basal ganglial and periventricular inflammation may calcify in the fetus.[56,163] Obstruction of the aqueduct of Sylvius or the foramen of Monro may result in hydrocephalus in congenital infection.

The enlarged lymph nodes in acute acquired toxoplasmosis show characteristic pathologic changes that may

warrant making a presumptive diagnosis.[57,209] Such changes include reactive follicular hyperplasia, epithelioid histiocytes encroaching on and blurring the margins of germinal centers, and distention of subcapsular and trabecular sinuses by monocytoid cells. Tachyzoites and cysts rarely are seen.[57]

In the eye, active chorioretinitis begins in the retina with severe inflammation and necrosis and exudation into the vitreous. Single or multiple foci occur, and secondary involvement of the choroid is always present. Tachyzoites and cysts have been found in these lesions.[20,172,176,177]

In immunocompromised hosts, widespread necrotizing lesions may be seen in the heart, muscle, brain, and other organs. These lesions, particularly those involving the CNS, have been found frequently with reactivation of toxoplasmosis in patients with acquired immunodeficiency syndrome (AIDS).[125]

IMMUNOLOGY

Cell-mediated immune responses are the major immunologic mechanisms that prevent reactivation of *T. gondii* in a chronically infected normal host.[32,45] Numerous effector mechanisms contribute to protection in murine models and human infection: $CD8^+$ cytotoxic T lymphocytes, $CD4^+$ T lymphocytes, monocyte oxidative mechanisms, production of interferon-γ by natural killer cells, and activation of macrophages by interferon-γ and tumor necrosis factor-α.* Killing of the parasite within activated macrophages is associated with the intracellular production of nitric oxide. Interleukin-2 and interleukin-12 enhance host resistance to *T. gondii;* interleukin-10 impairs the ability of macrophages to kill the parasite.[77]

In murine models, evidence exists for genetic determination of host resistance to infection.[21,22,129,139] Presence of the DQ3 allele seems to be associated with toxoplasmic encephalitis in patients with AIDS and hydrocephalus in infants with congenital toxoplasmosis.[22] Successful immunization of mice[23] and sheep[24,25] with *T. gondii* components and live tachyzoites of an "incomplete" strain[26] raises the possibility of developing a human vaccine.[98,140,214]

CLINICAL SYNDROMES

The disease in children may be considered in three categories: postnatally acquired, congenital, and ocular (which may be congenital or acquired).[171] Clinically apparent infection in older children may have been acquired recently or caused by reactivation of latent congenital or postnatally acquired infection. Congenital and acquired infections usually are subclinical, but congenital infection ultimately leads to serious sequelae in most cases.

Acute Acquired Toxoplasmosis

Acquired *Toxoplasma* infection is asymptomatic in most cases and frequently goes unrecognized because only 10 to 15 percent of infected individuals have clinical symptoms and signs. In certain outbreaks related to infection by oocysts, however, more than half of infected patients have been symptomatic.[204] The most common findings are lymphadenopathy and fatigue without fever.[132] The nodes are discrete and may or may not be tender. They do not suppurate. The groups of nodes most commonly involved are the cervical, suboccipital, supraclavicular, axillary, and inguinal. The adenopathy may be localized or involve multiple areas, including the retroperitoneal and mesenteric nodes. Uncommonly, the lymphadenopathy is accompanied by fever, malaise, fatigue, sore throat, and myalgia, a picture that closely simulates that of infectious mononucleosis but without serologic evidence of acute Epstein-Barr virus infection. The differential diagnosis of the lymphadenopathy often includes lymphoma. Chorioretinitis may develop during acute acquired infection, but it does not occur commonly.[130,153] The liver may be involved, and liver function test results may reflect hepatocellular damage. In individuals with normal immunologic function and no severe underlying disease, the infection usually is self-limited and rarely requires treatment.

In contrast, more severe and frequently fulminant infections are seen in patients receiving immunosuppressive therapy, in patients who have disease of the bone marrow or reticuloendothelial system, in patients with agammaglobulinemia, in recipients of bone marrow or stem cell transplants, and in patients with AIDS.* Encephalitis and rarely pneumonitis and myocarditis are the most important localized forms that may be encountered in immunocompromised patients. In toxoplasmic encephalitis, the predominant neurologic symptoms are headache, disorientation, and drowsiness. These symptoms may simulate aseptic meningitis or a mass lesion. In view of the various clinical manifestations of CNS involvement, it is important to consider toxoplasmosis whenever evidence of acute CNS disease is present.

Epidemiologic studies have suggested a correlation between *Toxoplasma* infection and a variety of neurologic and psychiatric illnesses in adults, including schizophrenia, suicide rates in women, and Alzheimer disease.[8,115,124] These intriguing findings require additional research before any conclusions can be reached.

Congenital Toxoplasmosis

Congenital infection usually is the result of an asymptomatic acute infection in the mother.[19,65] In a small proportion of cases, spontaneous abortion, prematurity, or stillbirth may result. Congenital toxoplasmosis has a wide spectrum of clinical manifestations but is subclinical in approximately 75 percent of infected newborns. When it is clinically apparent, it may mimic other diseases of the newborn.

Involvement of the CNS is a hallmark of congenital *Toxoplasma* infection. The presence of chorioretinitis, intracranial calcifications, and hydrocephalus is referred to as the classic triad of congenital toxoplasmosis. Fever, hydrocephalus or microcephaly, hepatosplenomegaly,

TABLE 223-1 **Vertical Transmission and Severity of Disease for *Toxoplasma gondii* by the Timing of Maternal Infection during Pregnancy**

	Trimester of Maternal Infection		
	First	Second	Third
Mild disease (%)	6	18	10
Overall transmission rate (%)	15	30	60
Proportion of infected children with specific disease severity			
Severe disease (%)	41	8	0
Stillborn or perinatal death (%)	35	7	0
Subclinical (asymptomatic) (%)	18	67	90

jaundice, convulsions, chorioretinitis (usually bilateral), cerebral calcifications, and cerebrospinal fluid (CSF) abnormalities (markedly increased protein concentration and mononuclear pleocytosis) are considered the classic features of severe congenital toxoplasmosis.[56,146,172] These manifestations occurred commonly in an early series of patients reported by Eichenwald[64] (Table 223-1). The case-fatality rate was 12 percent. In survivors in this series, sequelae included mental retardation in 86 percent; convulsions, spasticity, and palsies in almost 75 percent; and severely impaired vision in 60 percent.[64,74,180] Other occasional findings included rash (maculopapular, petechial, or both), myocarditis, pneumonitis and respiratory distress, hearing defects, an erythroblastosis-like picture, thrombocytopenia, lymphocytosis, monocytosis, and nephrotic syndrome. *Toxoplasma* has been detected in the inner ear and mastoid, with the associated inflammation resulting in deafness. An ascending flaccid paralysis with myelitis also has been reported.[172] These signs now are known to be most typical of the severe form of the infection in the absence of treatment.

The often subclinical nature of congenital toxoplasmosis in the newborn was shown in a French prospective study of 154 mothers who had acquired *Toxoplasma* infection during pregnancy and did not receive treatment.[52] Nine pregnancies (6%) ended in stillbirth, and 85 (55%) resulted in the birth of infected live-born infants. Of the live-born infants who were infected, 64 (75%) had subclinical infection, 14 (16%) had mild disease, and only 7 (8%) had clinically obvious severe disease at birth.[52,172]

The risk for transmission to the fetus varies significantly with the trimester of gestation in which the mother becomes infected. For untreated women, the rate is approximately 25 percent in the first trimester, 54 percent in the second trimester, and 65 percent in the third trimester; these figures are minimal estimates derived from placental isolation studies.[52] In contrast, the severity of clinical disease in congenitally infected infants is related inversely to the gestational age at the time of primary maternal infection (Table 223-2). In two studies from France,[40,52] severe disease or fetal or neonatal death occurred in approximately 40 to 79 percent of infants born to mothers with first-trimester infection, in 15 to

18 percent with second-trimester infection, and in 0 to 3 percent with third-trimester infection.

Another French prospective study of 210 congenitally infected infants born to mothers who were identified to have primary infection acquired during pregnancy revealed significant morbidity in 94 newborns.[40] Overall, 2 (0.9%) cases were fatal, 21 (10%) were severe, and 71 (33.8%) were mild; 116 cases were asymptomatic. Approximately 40 to 45 percent of the mothers in this study had been treated with spiramycin during pregnancy. These observations confirm that most congenital infections are subclinical at birth. Obvious manifestations occur infrequently. In the same study by Couvreur and associates,[40] 116 infants initially were thought not to be infected on the basis of a routine newborn physical examination. On more intensive examination, however, 39 (34%) of them were found to have one or more abnormalities. Twenty-two (19%) had abnormal CSF findings on lumbar puncture, 17 (15%) had chorioretinitis on indirect ophthalmoscopic examination, and 10 (9%) had intracranial calcifications on head radiographs or computed tomography (CT) scans. Guerina and colleagues[87] made remarkably similar observations in the congenitally infected newborns that they identified in New England by heel-stick blood sampling.

Some infected children without overt disease as neonates may escape serious sequelae of the infection; however, a significant number (24% to 85%) develop chorioretinitis, strabismus, blindness, hydrocephalus or microcephaly, cerebral calcifications, developmental delay, epilepsy, or deafness months or years later. Three studies provide data that define the incidence of these late sequelae.[112,113,116]

In a study from Paris,[116] 26,402 apparently healthy infants were tested routinely for serologic evidence of *Toxoplasma* infection at 10 months of age. Of these infants, 51 had positive serologic results for *Toxoplasma*, indicative of congenital infection. None had been treated for *Toxoplasma* infection in infancy. Of the 51, 5 were found to have chorioretinal scars by ophthalmologic examination, and chorioretinal lesions had developed in another 4 children by the time they reached 4 years of age, the longest period of follow-up. Some eventually lost functional vision in one eye. Three had intracranial calcifications.

Similarly, in a study from Holland in which a cohort of 1821 pregnant women were screened serologically, 12 congenitally infected infants were detected, and 11 of them were monitored for 20 years.[112,113] Of the 11, 5 were treated as neonates for 1 month only and 6 were not. Of the 5 treated infants, 4 had eye disease as neonates and 1 had parasites in CSF, which prompted therapy. Of these 11, 9 (82%) had chorioretinal scars by the time they reached 20 years of age, and 4 of them, including 2 who were initially normal, had severe visual impairment or blindness in one eye. The onset of disease leading to blindness occurred as late as 18 years of age. No neurologic or cognitive sequelae were observed.

The results of this prospective study are similar to those previously reported by Wilson and associates[220] from Alabama in a retrospective analysis of patients from the United States. During a mean follow-up period of 8.3 years, sequelae developed in 11 of 13 congenitally infected children (85%) who had no signs of disease on detailed examination in the newborn period. Sequelae included chorioretinal lesions in 11 children (85%), severe neurologic disability in 1 child (8%), and mental retardation in 2 children (15%). Sequelae first were noted at ages ranging from 1 month to 9 years. These 13 children were detected either as a result of routine screening of cord serum for IgM antibodies to *Toxoplasma*,[10] performed because acute *Toxoplasma* infection was diagnosed in the mother,[2,221] or as a result of nonspecific findings in the neonatal period (2 were small for gestational age and 1 had transient borderline thrombocytopenia).

That treatment may decrease the frequency or severity of sequelae is suggested by the Alabama and Paris studies, in which chorioretinitis developed only in untreated infants between 10 months and 4 years old. Taken together, these data indicate that most congenitally infected children who receive no or brief treatment, including children with inapparent infection as neonates, experience untoward sequelae during childhood. Current treatment regimens—prolonged for at least 1 year and often initiated before birth—seem to be associated with substantially less frequent and severe sequelae (see section on treatment).

Congenital toxoplasmosis may mimic or coexist with infection by other organisms. It must be differentiated from other perinatal infections caused by cytomegalovirus, herpes simplex virus, rubella virus, *Treponema pallidum* (syphilis), HIV-1, lymphocytic choriomeningitis virus, and certain bacteria (e.g., *Listeria*). Herpesvirus and cytomegalovirus infections, syphilis, and rubella may cause chorioretinitis; cytomegalovirus and HIV-1 infections may cause encephalopathies associated with cerebral calcifications. Degenerative encephalopathies and storage diseases in older children also may resemble congenital toxoplasmosis.

Many infants or preschool children with coexisting HIV infection and toxoplasmosis have been described.[147,148] In at least six of these patients, HIV and *Toxoplasma* infections seem to have been acquired in utero. Of these six patients, all but one had clinical evidence of CNS disease, and in most of these children, the CNS disease was associated with other findings common in congenital infection. These findings included hepatosplenomegaly, fever, and chorioretinitis and were evident at birth (one infant) or developed by the time the infant reached 4 months of age. Two of the other infants remained asymptomatic; one was treated for *Toxoplasma* infection and the other was not treated. One additional infant who acquired HIV infection at 18 months of age from a blood transfusion died at 5 years of age of toxoplasmic encephalitis. The findings in this patient resembled those in adults with AIDS and toxoplasmic encephalitis.[125] The advent of highly active antiretroviral therapy (HAART) along with the widespread use of trimethoprim-sulfamethoxazole for *Pneumocystis jiroveci* pneumonia prophylaxis has decreased greatly the frequency of clinical toxoplasmic encephalitis in children and adults with HIV infection.

Ocular Toxoplasmosis

In active congenital toxoplasmosis, the retinal lesions usually are bilateral.[88,146,161] In older children, chorioretinitis may involve only one eye and may be the sole manifestation of congenital toxoplasmosis. Toxoplasmic chorioretinitis, even in older children and adults, usually is considered to be the result of congenital infection.[153] A report of 38 children diagnosed with symptomatic chorioretinitis between 2002 and 2004 in the United Kingdom confirmed that 58 percent of cases were the result of congenital infection.[80] In some studies, *Toxoplasma* infection has accounted for 5 percent of severe visual impairments in children.[106] Active lesions on the fundus appear as white or yellowish foci with elevated, edematous margins surrounded by a zone of hyperemia (Fig. 223-3). Cells and fibrinous exudate in the vitreous may obscure the fundus. Older lesions appear as glial scars, and in areas in which the retina has been destroyed, the choroid and sclera are visible. Around the depigmented areas, deposition of pigment from the destroyed retina is present. The position of the lesion may be macular, juxtapapillary, or peripheral.

Patients may experience loss of central vision (caused by a perimacular lesion), hazy vision (caused by accumulated exudate), or "floaters" (caused by reactivation of peripheral foci). Neonates or infants with toxoplasmic eye disease may have microphthalmos, small corneas, posterior cortical cataract, anisometropia, strabismus, and nystagmus.[146,212] Strabismus and nystagmus in a child of any age should raise the possibility of congenital toxoplasmosis. The appearance of lesions in the fundus is not specific for toxoplasmosis. Similar lesions may occur with other, less common granulomatous diseases in the eye, such as toxocariasis, lymphocytic choriomeningitis, cat-scratch disease, and tuberculosis. Chorioretinitis may be recurrent, most commonly with reactivation at the margins of preexisting lesions.

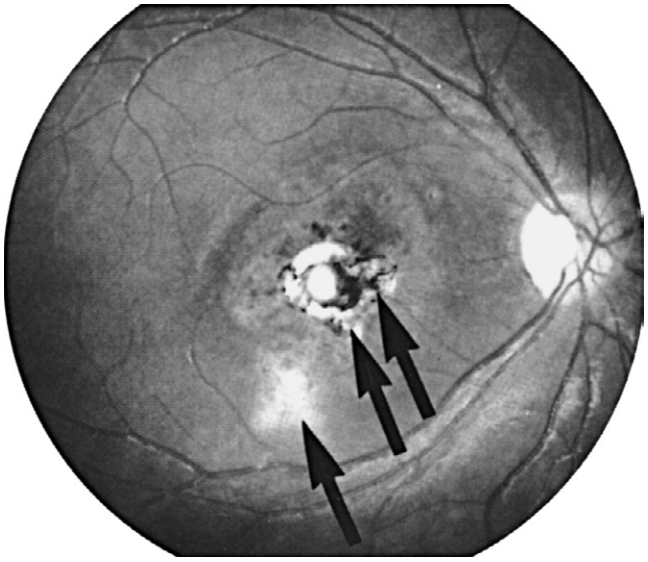

FIGURE 223-3 ■ Example of active and quiescent chorioretinitis caused by congenital toxoplasmosis in a 12-year-old patient. The active lesion *(single arrow)* is a satellite of an old chorioretinal scar *(two arrows)*. (From Mets M, Holfels E, Boyer KM, et al. Eye manifestations of congenital toxoplasmosis. *Am J Ophthalmol* 1996;**122**:309-24. Published with permission from the American Journal of Ophthalmology. LABORATORY DIAGNOSIS

Acute infection can be diagnosed by isolation of *T. gondii* from blood or body fluids; demonstration of tachyzoites in histologic sections of tissue or cytologic preparations of body fluids; characteristic lymph node histology; demonstration of *Toxoplasma* cysts in the placenta, fetus, or neonate; detection of the *Toxoplasma* genome by polymerase chain reaction (PCR) in body fluids; and characteristic serologic test results.[17,150,151,173,221] Each of these methods is discussed, but serologic tests are emphasized because they are the most common and readily available method to establish the diagnosis (Table 223-3).[221]

Serologic Methods

Measurements of IgG Antibody

The most useful tests for detection of IgG antibodies to *Toxoplasma* include the Sabin-Feldman dye test,[186] indirect immunofluorescent antibody (IFA) test, agglutination tests, and enzyme-linked immunosorbent assay (ELISA). Titers in ELISA are expressed in different terms for different commercial kits, precluding a discussion of IgG ELISA titers in relation to the diagnosis of acute infection.[55,213,221,226] In these tests, IgG antibodies appear within the first week of primary infection and reach peak titers (usually ≥1 : 500) within 1 to 2 months; detectable titers usually persist for life. Although the dye test is the most reliable method, it is available in only a few reference laboratories. Immunoblot compares well to the dye test and may detect antibody slightly earlier than other methods, but it is also not widely available.[104,120]

IFA test and ELISA are the most widely available and, when properly performed, yield results similar to those obtained with the dye test; however, many laboratories use commercially available kits that are not consistently reliable. Because the performance of kits varies greatly, clinicians must be familiar with the variations if they are comparing results from different laboratories.[120] Some sera that contain antinuclear antibodies yield false-positive IFA test results. The direct agglutination tests that currently are available use formalin-fixed tachyzoites or antigen-coated latex particles, are simple to perform, and are accurate.[194,221]

Initially after primary infection occurs, the avidity of IgG antibody for *T. gondii* antigen is low. Urea dissociates low-avidity antibodies, and a test has been developed that determines the percentage of antibodies that resist elution by 6 mol/L urea. This test is useful in the first 12 weeks of gestation in that the presence of high-avidity antibodies excludes the acquisition of infection in the previous 3 months.[26,221,225]

TABLE 223-3 **Guidelines for Interpretation of Serologic Tests for Toxoplasmosis**

IgG	IgM	IgG Avidity	Interpretation
Positive	Negative	—	Remote infection, immune. IgG avidity testing is best used when both IgG and IgM are positive and timing of infection is crucial, as in pregnancy (see below).
			For evaluation of infection in the newborn, false-negative IgM results occur in approximately 25% of cases. If infection is suspected in this setting, further testing (dye test, IgM EIA, IgA EIA, IgE EIA/ISAGA, PCRs, ideally with paired maternal serologies—see text) is necessary in a reference laboratory (*Toxoplasma* Serology Laboratory, Palo Alto Medical Foundation, 860 Bryant Street, Palo Alto, CA 94301, 415-326-8120).
Positive	Positive or equivocal	High	Infection within the past 18 mo but likely >12 wk ago. If pregnant and beyond first trimester, consider sending specimen to reference laboratory for dye test, repeat IgG avidity and IgM EIA, IgA EIA, IgE EIA/ISAGA, and AC/HS testing (see above).
Positive	Positive or equivocal	Low	Infection within the past 12 wk. Consider sending specimen to a reference laboratory (see above) to time infection more accurately (dye test, repeat IgG avidity and IgM EIA, IgA EIA, IgE EIA/ISAGA, and AC/HS) in the setting of pregnancy.
Equivocal	Negative	—	Indeterminate. Test a new specimen or consider a different assay (IFA or ELISA).
Equivocal	Equivocal	—	Indeterminate. Test a new specimen or consider a different assay (IFA or ELISA).
Equivocal	Positive	—	Acute infection or false-positive IgM result. Test a second specimen; if IgG becomes positive or remains equivocal, consider sending specimen to a reference laboratory to time infection more accurately (dye test, IgG avidity, IgM EIA, IgA EIA, IgE EIA/ISAGA, AC/HS—see text) in the setting of pregnancy.
Negative	Negative	—	No evidence of *Toxoplasma* infection. Not immune.
Negative	Equivocal	—	Either false-positive IgM result or possible recent infection. Obtain a new specimen and retest. If infection is recent, IgM and IgG should become positive, with low IgG avidity. If repeated testing is still IgG negative and IgM equivocal, patient is likely uninfected. Consider IgM ISAGA.
Negative	Positive	—	Acute infection or false-positive IgM result. Repeat testing on new specimen. If the result is the same, it is likely a false-positive IgM result. Consider IgM ISAGA.

AC/HS, Differential agglutination test; *EIA,* enzyme immunoassay; *ELISA,* enzyme-linked immunosorbent assay; *IFA,* immunofluorescence assay; *ISAGA,* immunosorbent agglutination assay; *PCR,* polymerase chain reaction.

Other tests vary in their reliability. Indirect hemagglutination is widely available, but the results frequently are negative in newborns with congenital infection.[221] This test should *not* be used for screening of pregnant women because detectable increases in titer are delayed compared with the increases detected by ELISA and by the dye, IFA, and agglutination tests. Meaningful interpretation of changes in titer on sequential sera requires that assays on each sample be performed in the same run by a reliable laboratory.[221]

Measurements of IgM Antibody

IgM antibodies are detected most commonly by the IgM IFA test, IgM immunosorbent agglutination assay (ISAGA), or IgM ELISA. IgM antibodies appear in the first week of primary infection and peak within 1 month.[158] Depending on the sensitivity of the method used, IgM antibodies may be demonstrable for 2 to 3 months or 1 year or longer. This prolonged presence of IgM leads to the most common diagnostic error in pregnant women—the assumption that a positive IgM result indicates fetal exposure, when the maternal infection may have occurred well before pregnancy began. IgM ELISA and IgM ISAGA are much more sensitive than the IgM IFA test. Absence of IgM ELISA or IgM ISAGA antibodies in an immunologically normal older child (>1 year old) or adult essentially rules out a recently acquired infection.[220] A negative IgM IFA test result is not as sensitive in ruling out recently acquired infection. Of sera that were negative with the IgM IFA test and obtained from adults who had acquired toxoplasmosis recently, 93 percent were strongly positive in IgM ELISA.[157] IgM IFA testing detects specific IgM antibody in only 25 percent of infants with proven congenital infection, whereas IgM ELISA detects antibody in approximately 75 percent of such cases.[157] The presence of rheumatoid factor or antinuclear antibodies may cause false-positive results in IgM IFA testing.[2]

The "double-sandwich" IgM ELISA avoids the false-positive results caused by the presence of rheumatoid factor, which the infant can produce in utero, and the false-negative results caused by competition from the high levels of maternal IgG antibody that occur in the IgM IFA test.[156,221] In addition, the false-positive results in the IgM IFA test caused by antinuclear antibodies are not found in IgM ELISA.[2,156]

ISAGAs are used widely in Europe. Similar to IgM ELISA, they capture IgM on a solid surface, detect specific IgM, and involve the addition of whole formalin-fixed organisms or *Toxoplasma* antigen–coated latex particles.[54,170] These assays are available commercially

and give results comparable to those of IgM ELISA, are simpler to perform, and do not require expensive equipment.

Measurements of IgA and IgE Antibodies

Demonstration of IgA and IgE antibodies in the fetus or newborn by ELISA and ISAGA seems to be at least comparable to the demonstration of IgM antibody in sensitivity for the diagnosis of congenital *Toxoplasma* infection.[48,167,197,223] The IgA test also seems to be more sensitive than the IgM test for detection of acquired infection. Specificity remains an issue, however, so neither IgA/IgE ELISA nor IgA/IgE ISAGA has superseded the IgM test for diagnosis of acquired infection. IgA and IgE antibodies persist longer than IgM antibodies and may be useful in cases of subacute illness or when IgM titers are low.

Differential Agglutination

Acetone-fixed and formalin-fixed *T. gondii* tachyzoites may yield differing agglutination titers, depending on the acuity of the infection. The test based on this phenomenon is called the AC/HS differential agglutination test.[44] In general, a disproportionately high agglutination titer with acetone-fixed organisms suggests acute infection; a disproportionately high titer with formalin-fixed organisms suggests chronic infection. Interpretative norms for this test have been established.[44] This test, when it is combined with the dye test, IgM ELISA, IgA ELISA, IgE ELISA/ISAGA, and avidity studies, yields a "toxoplasmic serologic profile" that permits the most accurate evaluation of infection acuity in pregnant women,[152,221,224] and often it can resolve any inconclusive or discrepant results obtained in a hospital or commercial laboratory.

Nonserologic Methods

Nonserologic methods are used less commonly to establish the diagnosis of *Toxoplasma* infection because they are not widely available and require tissue specimens.[188]

Isolation of the Organism

Isolation of *Toxoplasma* from blood or body fluids (e.g., CSF) establishes that the infection is acute. In the case of a neonate, isolation from the placenta or the infant's tissues is sufficient to diagnose congenital *Toxoplasma* infection. In 90 percent of placentas from which *T. gondii* is isolated, congenital infection occurs.[172] Sensitivity of placental detection of *Toxoplasma* by isolation for the diagnosis of congenital infection appears to vary, with reports from 25 to 67 percent, and depends on the trimester of acquisition of infection.[66,174] Isolation of *Toxoplasma* from the tissues of older children or adults may reflect, however, only the presence of latent infection (cyst form). The organism may be isolated by inoculation of body fluids, leukocytes, or tissue specimens into the peritoneal cavities of mice or into tissue cultures. Specimens should be processed and inoculated immediately; however, tissue and blood may be stored at 4° C (39° F) overnight. Freezing and thawing or formalin treatment kills the organism. Establishment of definitive diagnosis by isolation of *Toxoplasma* from tissues usually takes 4 to 6 weeks by mouse inoculation; tissue culture is less sensitive for recovery of *Toxoplasma*, but the results are available sooner.

Histology

Demonstration of tachyzoites, but not cysts, in tissue sections or smears of body fluids (e.g., CSF) establishes a diagnosis of acute infection. The organism may be difficult to see with routine stains. The peroxidase-antiperoxidase technique is exquisitely sensitive and has been used with a high degree of sensitivity and specificity to show the organism in the CNS of patients with AIDS.[55] In older children and adults, the histopathologic changes in toxoplasmic lymphadenitis are sufficiently distinctive to enable pathologists to make a presumptive diagnosis of acute acquired toxoplasmosis (see section on pathology).[57,209] Histologic demonstration of cysts establishes that a patient has *Toxoplasma* infection, but they are diagnostic of toxoplasmosis only in the placenta, fetus, or newborn.

Antigen-Specific Lymphocyte Transformation

Lymphocyte transformation in response to *Toxoplasma* antigens is a specific and sensitive indicator of previous *Toxoplasma* infection in adults and has been used successfully to diagnose congenital *Toxoplasma* infection in infants 2 months or older.[136,199,218] Lymphocyte transformation often is absent in the newborn period, however, particularly in more severely affected infants, because of specific immune tolerance.[136,143]

Polymerase Chain Reaction

Amplification of the B1 genome of *T. gondii* DNA by PCR permits detection of the parasite in body fluids or tissues such as CSF, amniotic fluid, and lymph nodes.* Experience with the test in France, where PCR analysis of amniotic fluid was compared with the results of percutaneous umbilical blood sampling in 339 pregnant women, has shown that agreement of the two methods is almost 100 percent for the diagnosis of intrauterine infection.[89] In view of the considerably lower risk accompanying amniocentesis than with percutaneous umbilical blood sampling and the fact that amniocentesis potentially can be performed earlier in gestation, this diagnostic procedure seems to be a major advance in prenatal diagnosis. An early prospective study in France has shown, however, that only 48 (64%) of 75 amniotic fluid specimens from congenitally infected infants were positive by PCR analysis of a single sample obtained soon after maternal seroconversion. The test had a 100 percent positive predictive value, but a single negative assay did not rule out fetal infection.[183] A more recent report from the same institution on real-time PCR analysis of

*References 33, 86, 89, 182, 183, 209.

amniotic fluid of 261 acutely infected pregnant women indicated an overall sensitivity of 92 percent and a negative predictive value of 98 percent, with specificity and positive predictive values of 100 percent.[211]

A more recently developed nucleic acid amplification test, the loop-mediated isothermal amplification method, uses the same general principle as conventional PCR but may offer a simpler and less expensive alternative if initial encouraging reports are confirmed prospectively.[118]

Interferon-γ Release Assay

In recent years, interferon-γ release assays on whole blood have been approved for the diagnosis of latent tuberculosis infection. A report from France suggests that this same technique, using *T. gondii* antigen instead of *Mycobacterium tuberculosis* antigens to stimulate white blood cells and then measuring the release of interferon-γ, has a sensitivity of 94 percent and a specificity of 98 percent for diagnosis of congenital toxoplasmosis.[34]

Diagnosis in Specific Clinical Situations

Acute Acquired Toxoplasmosis

If IgM and IgG antibodies are not detectable, the diagnosis of acute *Toxoplasma* infection in an immunocompetent child virtually is excluded.[216,221] The diagnosis of recently acquired infection is confirmed if seroconversion from a negative to a positive titer is noted or if a serial fourfold increase in titer to high levels is observed when sera drawn at 3-week intervals are run in parallel. A single high titer in any test is not diagnostic. A dye test or IFA titer of 1:500 or greater in the presence of a high IgM antibody titer probably is diagnostic of recent acute infection. Because IgM can remain positive for 18 months after acute infection, a serum IgG avidity test can be performed to time the infection more accurately. Low IgG avidity suggests that infection has occurred within the past 12 weeks, whereas high avidity suggests more remote infection. The absence of IgM antibodies in IgM ELISA or IgM ISAGA essentially excludes the diagnosis of acute infection. In contrast, the absence of IgM antibodies in the IgM IFA test does not mean that the infection is not acute; in one series, 25 percent of results in adults with acute infection were negative by the IgM IFA test.[157]

Toxoplasma *Infection in Immunodeficient Children*

Serologic tests should be done to identify individuals at risk for acquiring toxoplasmosis, such as recipients of organ, stem cell, and bone marrow transplants. The available serologic tests may be inadequate to detect acute active infection in some immunodeficient patients because their antibody response may be abnormal, which is especially the case in stem cell and bone marrow transplant recipients.[50,131] Experience in the Palo Alto, California, reference laboratory has revealed that acute infection may be present in patients with AIDS and in bone marrow transplant recipients without any demonstrable IgM antibody and in some immunocompromised patients who have little or no IgG antibody.[126] In patients with AIDS and active *Toxoplasma* infection, antibody titers in the modified direct agglutination test[55] may be elevated in the presence of low or undetectable titers in the dye or IFA test.[133] These and other immunodeficient patients can have progressive, lethal toxoplasmosis. In almost all cases, encephalitis, brain abscesses, or both are the predominant findings; hepatic involvement, pneumonitis, and myocarditis may be present. A high index of suspicion is necessary in these patients, and immunoperoxidase staining of appropriate biopsy specimens often is required to establish the diagnosis. Real-time PCR may be a valuable aid in these situations, although tissue immunoperoxidase staining remains the most reliable test.[33]

Toxoplasma *Infection in Pregnant Women*

Toxoplasma infection acquired during pregnancy is associated with clinical signs (e.g., lymphadenopathy) in only 10 to 15 percent of patients. The fetus is at risk, however, for contracting the infection regardless of whether the mother is symptomatic. To detect acute infection in a pregnant woman in the absence of a routine screening program in which serologic tests are performed periodically throughout pregnancy, a suitable test for IgM antibody (IgM ELISA or IgM ISAGA) should be performed if other serologic test results are positive at any titer. If a suitable IgM antibody test is unavailable and the original serum contains IgG antibodies, the IgG antibody test should be repeated in 3 weeks, in parallel with the original serum, to determine whether the titer is stable or increasing.[173,221] More recent experience with IgG avidity testing on a single maternal specimen suggests that this additional tool may be helpful in attempting to define maternal infection as acute (within the previous 12 weeks) or remote.[26,173]

If the IgM ELISA or IgM ISAGA result is negative and the IgG antibody titer is stable and less than 1:500, no further evaluation is necessary. Because IgG titers usually stabilize at high levels (e.g., the dye test or IFA titer ≥1:500) at 6 to 8 weeks or longer after acquisition of the infection, if the dye test or IFA titer is 1:500 or less and stable (regardless of IgM antibody titer), infection was acquired at least 4 weeks and probably more than 8 weeks before the serum was obtained. In the United States, an asymptomatic woman commonly is evaluated for the first time more than 8 weeks after conception, however. If her dye test or IFA titer is 1:500 or greater, her IgM ELISA or IgM ISAGA result is negative, and no significant increase in titer in any test can be shown, her infection almost certainly was acquired before conception. In women with elevated IgM titers or increasing IgG titers, infection possibly was acquired during pregnancy. A complete toxoplasmic serologic profile[152] in a reference serologic laboratory is recommended to settle the question.

Fetal Diagnosis

As noted earlier, severe disease almost always is associated with primary maternal infection in the first or second

trimester of pregnancy, but only 25 percent and 54 percent of such maternal infections result in fetal infection. These rates in exposed fetuses may be reduced by half by maternal treatment with spiramycin. Identification of cases in which the fetus already is infected permits a parental decision to terminate the pregnancy or to treat the fetal infection more aggressively with pyrimethamine-sulfadiazine.

Studies by workers in Paris have established an approach that allows definitive diagnosis and treatment of fetal infection in utero.[42,53,89,168] These researchers initially sought to establish the diagnosis of fetal infection at 20 to 29 weeks of gestation by isolation of *Toxoplasma* from amniotic fluid or from fetal blood obtained by percutaneous umbilical blood sampling and use of the sensitive mouse inoculation method. Prenatal diagnosis was attempted in 746 pregnancies in which seroconversion occurred near the time of conception or before the 26th week of gestation. In 39 of these pregnancies, fetal infection was diagnosed in utero. *Toxoplasma* was isolated from fetal blood alone in 12 cases, from amniotic fluid alone in 7 cases, and from both in 15 cases, for a total of 34. *Toxoplasma*-specific IgM antibodies were detected in fetal blood in only 9 cases with the highly sensitive ISAGA, and none was positive before 24 weeks of gestation. By follow-up examination until 3 months post partum or by examination of aborted fetal tissue, a total of 42 cases were proved to have been infected. These researchers were able to detect 39 (93%) of 42 cases of fetal infection occurring before the 26th week of gestation; no false-positive diagnoses occurred.

These investigators subsequently extended their series and reported that a definitive diagnosis of infection was established in utero in 80 (90%) of 89 cases in which the fetus was infected.[90] These results may not be reproduced easily by other investigators for various reasons: monthly monitoring for new maternal infection to detect maternal infection soon after it occurs, sampling of fetal blood and amniotic fluid on more than one occasion, the use of optimal laboratory methods and conditions, and experience in these procedures.

With the use of PCR to amplify the B1 gene of *Toxoplasma* in amniotic fluid obtained after 18 weeks of gestation, these same investigators were able to achieve a sensitivity and specificity for the diagnosis of fetal infection that approached 100 percent.[89] In the most recent multicenter collaborative French study, in which a single specimen was prospectively studied in 261 pregnant women with acute toxoplasmosis, the specificity and positive predictive value remained 100 percent, with a sensitivity of 92 percent and a negative predictive value of 98 percent.[211] The sensitivity and specificity of this test as specimens currently are processed and handled in the United States remain to be determined.

Most of the mothers in these French studies had received treatment with spiramycin soon after primary maternal infection was diagnosed, with the intention of continuing therapy until delivery. In contrast to its beneficial effect on maternal-to-fetal transmission, spiramycin does not seem to decrease the severity of fetal infection after it has been established. The impetus for proving fetal infection in early to middle gestation is to allow intervention either to terminate the pregnancy or to treat the fetus more aggressively. In an extended series of 89 infected fetuses reported by Hohlfeld and colleagues,[90] 34 pregnancies were terminated at the request of the parents. In each of these cases, which were selected either for detectable CNS disease on ultrasound examination or for onset of maternal infection before 12 weeks of gestation, brain necrosis was found on examination of tissue.

These data indicate the value of specifically identifying fetuses that truly are infected and are at high risk for acquiring severe disease because selective termination of these pregnancies allowed successful completion of most pregnancies in which fetal infection did not occur. In addition to the 34 terminated pregnancies with proven fetal infection, 52 pregnancies with 55 offspring were carried to term. In these 52 pregnancies, 43 had fetal infection proven prenatally, and 9 additional offspring were found to be infected by postnatal examination. In the 43 pregnancies in which prenatal diagnosis of fetal infection was established, more aggressive therapy with pyrimethamine and a sulfonamide compound alternating with spiramycin was given in the latter part of pregnancy. This treatment seemed to decrease the number of parasites, as indicated by an approximate 50 percent reduction in the fraction of placentas from which *Toxoplasma* was isolated at delivery compared with cases in which no treatment or spiramycin alone was given.

Regarding clinical outcome, the authors interpreted their data to indicate that such treatment decreased the incidence of severe disease.[90] This conclusion was based, however, on a retrospective comparison with a group of historical controls in which data regarding fetal deaths and termination of pregnancy were unavailable. Because pregnancies with proven or probable severe fetal infection were terminated selectively at the parents' request, one cannot conclude with certainty that the outcome of the infants born to mothers with first-trimester infection was improved by the administration of more aggressive therapy; the outcome of infants born to mothers with second-trimester infection seems to have been improved.[217] A meta-analysis of selected published cohorts on prenatal treatment of congenital toxoplasmosis showed only a weak association between early treatment and a reduced risk of acquiring congenital toxoplasmosis.[202] However, a more recent report of an observational cohort from the European Multicentre Study on Congenital Toxoplasmosis (EMSCOT) showed a significant reduction in serious neurologic sequelae for children with congenital toxoplasmosis who were treated prenatally, with the most significant impact for those women who seroconverted in the first 10 weeks of gestation.[36] Variations in outcomes for such studies need to be interpreted in light of the observation that the disease impact for toxoplasmosis varies across geographic regions, possibly related to virulence characteristics of different strains of *T. gondii* as well as other factors.[207]

It would be desirable to have data from studies in which the effects of such therapy are compared directly in a randomized, concurrent study[205,206]; such studies are unlikely to be performed, however. Nonetheless, these published studies have established the utility of an

aggressive approach to prenatal diagnosis in allowing physicians to make an accurate, early diagnosis of fetal infection. If the fetus is infected and affected, as determined by ultrasound examination, a decision for selective termination of pregnancy can be made rationally. Aggressive therapy with pyrimethamine-sulfadiazine may be offered in cases in which termination is not considered desirable, and it may improve the outcome.

Diagnosis of Congenital Toxoplasmosis after Birth

A thorough clinical and laboratory examination is necessary to evaluate fully the existence and extent of congenital toxoplasmosis in a newborn (Table 223-4). Demonstration of IgM, IgA, or IgE antibody in an infant's blood or CSF at any time is diagnostic of congenital infection if contamination by maternal blood can be reasonably excluded.[221] Specimens obtained after the infant reaches 10 days of age are more reliable in this regard. If the much less sensitive IgM IFA test is used, the presence of antinuclear antibody and rheumatoid factor also must be excluded. As mentioned earlier, the detection rate of congenitally infected infants is 25 percent for the IgM IFA test and 75 percent for IgM ELISA and IgM ISAGA. Data are insufficient for predicting how often IgA and IgE antibodies are detected. IgM antibodies may be demonstrable in the first few days of life or may appear at variable times after birth. Investigators from France recently reported on their use of likelihood ratios of the various tests used to confirm congenital infection in 767 children born after acute maternal toxoplasmosis during pregnancy. The probability of a child's being infected was essentially 100 percent if the amniotic fluid was PCR positive and the IgM was positive in the newborn baby.[169] If both test results were negative, there was still a 10 percent probability of infection in their cohort.

If *Toxoplasma* is not isolated and IgM, IgA, or IgE antibodies are not detected, follow-up serologic testing is the only means of establishing the diagnosis. Maternally transmitted IgG antibodies may persist for 6 to 12 months or longer, depending on the original titer. The higher the original titer, the longer maternal antibody is detectable in the infant. The presence of IgG antibody at 8 to 12 months of age does not prove that the infant is infected. Synthesis of IgG *Toxoplasma* antibody usually can be shown by the third month of life if the infant is not treated; it may be delayed until the sixth or ninth month if the infant is treated. At the time that the infant begins to synthesize IgG antibody, infection may be documented by computing the specific "antibody load"—the ratio of specific serum antibody titer to the level of serum IgG in the infant.[172] In the absence of infection, the antibody load decreases in the second or third month as the infant begins to produce IgG that does not contain specific *Toxoplasma* antibodies. In the presence of *Toxoplasma* infection, the infant produces specific antibodies, and the antibody load remains the same or increases. Most infected infants who are treated during the first year of life have a substantial increase in antibody after termination of therapy (serologic rebound).[210] This phenomenon permits the diagnosis to be confirmed in some uncertain cases.

TABLE 223-4 Evaluation of a Neonate When Serology of the Mother or Illness of the Neonate Indicates That a Diagnosis of Congenital Toxoplasmosis Is Suspected or Probable

In addition to a careful general examination, the infant is examined by the following:

Clinical Evaluation and Nonspecific Tests

Pediatric ophthalmologist
Pediatric neurologist
Brain CT (data suggest excellent agreement between CT and ultrasonography,[117] which can be obtained more quickly and without the need for sedation)
Blood tests
Complete blood cell count with differential and platelet counts
Serum total IgM, IgG, IgA, and albumin
Serum alanine aminotransferase, total and direct bilirubin
CSF cell count, glucose, protein, and total IgG

***Toxoplasma gondii*–Specific Tests**

Newborn serum analyzed for antibody detected by Sabin-Feldman dye test, IgM ISAGA, IgA EIA, IgE EIA/ISAGA (0.5 mL serum to *Toxoplasma* Serology Laboratory, Palo Alto Medical Foundation, 860 Bryant Street, Palo Alto, CA 94301, 415-326-8120)
Newborn blood for inoculation into mice (1-2 mL clotted whole blood in red-topped tube to *Toxoplasma* Serology Laboratory)
Lumbar puncture: CSF dye test and IgM EIA (0.5 mL CSF to *Toxoplasma* Serology Laboratory); consider PCR (1 mL frozen CSF to *Toxoplasma* Serology Laboratory)
Sterile placental tissue (100 g in saline, from fetal side near insertion of cord, no formalin, to *Toxoplasma* Serology Laboratory for subinoculation)
Maternal serum analyzed for antibody detected by dye test, IgM EIA, IgA EIA, IgE EIA/ISAGA, and AC/HS

AC/HS, Differential agglutination test; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *EIA,* enzyme immunoassay; *ISAGA,* immunosorbent agglutination assay; *PCR,* polymerase chain reaction.
Modified from McLeod R, Wisner J, Boyer K. Toxoplasmosis. In: Krugman S, Katz SL, Gershon AA, editors. Infectious diseases of children. *St. Louis: Mosby; 1992, p. 539.*

Ocular Toxoplasmosis

Toxoplasma has been estimated to cause 35 percent of cases of chorioretinitis in the United States and central and western Europe.[92,188,203] Acquired toxoplasmosis usually is not accompanied by chorioretinitis. Most cases are thought to result from congenital infection that does not become clinically apparent until after reactivation. This event occurs most commonly in adolescence. Although the presence of chorioretinitis should prompt a search for *Toxoplasma* infection, proof that *Toxoplasma* caused the eye disease often is lacking. The titer of antibody in serum does not correlate with the presence of active lesions in the fundus. Low titers of IgG antibody are the usual finding in patients with reactivation

Toxoplasma chorioretinitis. IgM antibodies generally are absent.

Toxoplasma probably is excluded as a cause of chorioretinitis if the results of serologic tests are negative in undiluted serum. If the retinal lesions are characteristic and serologic test results are positive, the diagnosis is probable. If the retinal lesions are atypical and the serologic test results are positive, the diagnosis of *Toxoplasma* chorioretinitis is less certain because of the increasing prevalence of *Toxoplasma* antibodies with age in the normal population. Finding *Toxoplasma* antibodies in the child's mother supports the possibility of congenital infection, as does detection of intracranial calcification on CT scan of the patient. Demonstration of local antibody production in aqueous humor obtained by paracentesis of the anterior chamber can be used to establish the diagnosis of *Toxoplasma* chorioretinitis in equivocal cases.[172,221] The risk of this procedure in a situation of threatened vision, weighed against the low risk of a short course of treatment, is such that it seldom is performed.

TREATMENT

The need for therapy and the duration of therapy are determined by the nature and severity of the clinical illness and by the immune status of the infected patient. Antibody titers are not useful indicators of therapeutic response, and an increasing antibody titer soon after discontinuation of therapy (serologic rebound) is not an indication of therapeutic failure. Specific therapy acts primarily against the tachyzoite form; the drugs currently available do not eradicate the encysted form containing bradyzoites. Close, longitudinal follow-up and supportive interventions are crucial contributors to therapeutic success.

Therapeutic Agents

The therapeutic agents used, their dosages, and indications for their use in the management of toxoplasmosis are included in Table 223-5 and discussed next.

Spiramycin

Spiramycin is a macrolide that has been used extensively in Europe to reduce transmission of infection from an acutely infected mother to the fetus in utero.[37] It is concentrated in the placenta and is reported to reduce transmission by 50 to 60 percent. It reduces the ability to isolate the organism from the placentas of definitively infected newborns from 95 to 80 percent.[39] Spiramycin is less effective than pyrimethamine-sulfadiazine in the treatment of congenital infection and toxoplasmic encephalitis.[38,39,51,189,190] Toxoplasmic encephalitis has developed in patients receiving spiramycin and has been treated effectively with pyrimethamine-sulfadiazine. Toxicities include allergic manifestations, gastrointestinal intolerance, and paresthesias.

Spiramycin apparently does not treat manifestations of *T. gondii* infection in the fetus in utero.[39,51,90,189] It formerly was used in alternate-month regimens with pyrimethamine and sulfadiazine for treatment of congenital toxoplasmosis in France.[172] Spiramycin is not approved by the U.S. Food and Drug Administration but may be obtained with compassionate clearance by calling 301-827-2127. The manufacturer (Aventis-Pasteur) provides the drug after the diagnosis has been documented and Food and Drug Administration forms have been completed.

Pyrimethamine

Pyrimethamine has been shown to be effective against *T. gondii* in vitro,[142,145] in animal models,[72] and in human infections.* When it is used in conjunction with sulfadiazine, synergy can be shown. The pharmacokinetics of pyrimethamine has been studied in infants and adults.[145,215] Pyrimethamine is metabolized in the liver. Its pharmacokinetics is not altered by renal insufficiency but is affected by concomitantly administered drugs (e.g., phenobarbital). Pyrimethamine toxicities include reversible marrow suppression (most commonly) and allergy. Aplastic anemia, hepatotoxicity, and various allergic manifestations (including Stevens-Johnson syndrome) also have been listed as toxicities of this medication. Pyrimethamine always should be administered in conjunction with leucovorin (i.e., folinic acid) because human cells can use folinic acid for synthesis of nucleic acids but *T. gondii* cannot.[145]

Leucovorin

Leucovorin (folinic acid) always is administered during treatment with pyrimethamine. Folinic acid has a protective effect for human cells that folic acid does not. Increased doses of leucovorin are used in the event of marrow suppression. Because of the long half-life of pyrimethamine, continuation of leucovorin therapy for 1 week after discontinuation of pyrimethamine is recommended.

Sulfadiazine, Sulfamerazine, and Sulfamethazine

The three sulfonamides sulfadiazine, sulfamerazine, and sulfamethazine (known as triple sulfa when used in combination) are the most active of the sulfonamides against *T. gondii* and are synergistic with pyrimethamine in their activity against *T. gondii*. Of the three, only sulfadiazine is available in the United States. All other sulfonamides are less active in vitro.[142] The sulfonamides are excreted by the kidney, and the dosage must be adjusted for patients with renal insufficiency. Nephrolithiasis can occur in older children and adults, in whom urinary acidification is more effective, and fluid requirements are lower on a weight basis than in infancy. The risk for development of stones in these groups can be reduced by aggressive fluid supplementation (1 to 2 L above maintenance) and urine alkalinization.[29] In older children who weigh more than 20 kg, a dose of 75 mg/kg/day (rather

*References 41, 43, 72, 128, 145, 224.

TABLE 223-5 **Treatment of Toxoplasmosis**

Disease	Medication	Dosage	Length of Therapy
Acute acquired—generally not treated unless severe or persistent symptoms, vital organ damage, or host is immunosuppressed	Pyrimethamine *plus*	2 mg/kg/day for 2 days, then 1 mg/kg/day	4-6 wk or 2 wk after symptoms resolve for normal host; 4-6 wk beyond resolution for immunosuppressed hosts. In AIDS, treat until $CD4^+$ count >200.
	Sulfadiazine *plus*	75-100 mg/kg/day divided twice daily (maximum 4 g/day); consider the lower dose in children >20 kg (see text)	
	Folinic acid	5-20 mg 3 times weekly; use higher doses if marrow suppression	
Ocular, older child	Pyrimethamine *plus*	2 mg/kg/day for 2 days, then 1 mg/kg/day (maximum 50 mg/day)	4-6 wk or 2 wk after symptoms resolve
	Sulfadiazine *plus*	75-100 mg/kg/day divided twice daily (maximum 4 g/day); consider the lower dose in children >20 kg (see text)	Prednisone should be continued until resolution of sight-threatening active chorioretinitis
	Folinic acid *plus*	5-20 mg 3 times weekly	
	Prednisone	1 mg/kg/day divided twice daily	
Congenital	Pyrimethamine *plus*	2 mg/kg/day for 2 days, then 1 mg/kg/day for 6 mo, then 3 times weekly (M-W-F) for 6 mo	1 yr
	Sulfadiazine *plus*	100 mg/kg/day divided twice daily	
	Folinic acid *plus*	5-10 mg 3 times weekly	
	Prednisone	1 mg/kg/day divided twice daily	Until resolution of elevated CSF protein level or sight-threatening active chorioretinitis
Pregnant women—acute infection first 21 wk of gestation	Spiramycin	3 g/day divided twice daily without food	Until fetal infection documented or excluded at 21 wk of gestation; if fetus infected, change to pyrimethamine plus sulfadiazine plus folinic acid until delivery
Pregnant women—fetal infection confirmed (amniotic fluid PCR positive)	Pyrimethamine *plus*	100 mg/day divided twice daily for 2 days, then 50 mg/day	Until delivery
	Sulfadiazine *plus*	3 g/day divided twice daily	
	Folinic acid	5-20 mg/day	

AIDS, Acquired immunodeficiency syndrome; *CSF,* cerebrospinal fluid; *PCR,* polymerase chain reaction.

than the conventional 100 mg/kg/day) should be considered because this dose more closely approximates the calculated adult dose based on body surface area. Other sulfonamide toxicities include allergy (including Stevens-Johnson and DRESS syndromes), marrow suppression, and hepatotoxicity.[141] Sulfonamide pharmacokinetics has been studied in infants.[172]

Clindamycin

Although the effect of clindamycin is delayed, it does have an effect in vitro against *T. gondii* with prolonged time in culture.[165] It also has been shown to be effective in murine models. Clindamycin has been found to be comparable in efficacy to sulfadiazine for the treatment of toxoplasmic encephalitis in adult patients with AIDS when it is used in a combined high-dose regimen with pyrimethamine.[43,128] High-dose pyrimethamine also is effective alone. It was not compared directly with the other two regimens in the latter study.

Other Antimicrobial Agents

Numerous other antimicrobial agents have been shown to be effective in vitro or in animal models against either tachyzoites or encysted bradyzoites,[3-6,91,93] but their role, if any, in the treatment of human disease remains to be defined. Atovaquone (5-hydroxynaphthoquinone) was effective against bradyzoites within cysts in vitro.[93] Forty percent of patients with AIDS had a relapse of toxoplasmic encephalitis, however, while being treated with this antimicrobial agent. Other antimicrobial agents with an effect on *T. gondii* in vitro or in vivo include cycloguanil[91]; artemisinin[91]; pyrimethamine-sulfadoxine (Fansidar)[142]; rifabutin[7]; trovafloxacin (no longer available owing to liver toxicity)[108]; and the newer macrolides

clarithromycin, azithromycin, and roxithromycin.[3,5,6] Isolated reports of clinical use of some of these agents, most typically when standard agents are not available or not tolerated, have appeared in the literature with mixed results.

Because the activity of sulfamethoxazole is less than that of sulfadiazine, trimethoprim-sulfamethoxazole has been considered less effective for treatment of toxoplasmosis. Many investigators have used this combination successfully, however, to treat toxoplasmic encephalitis in adults with AIDS. Doses of trimethoprim-sulfamethoxazole, as used to prevent *P. jiroveci* pneumonia in the context of HIV infection, also seem to prevent episodes of reactivated toxoplasmosis.[27] A randomized controlled trial has shown that trimethoprim-sulfamethoxazole is as effective as pyrimethamine-sulfadiazine in the treatment of isolated ocular toxoplasmosis in young adults.[195] Pyrimethamine combined with sulfadoxine, despite having lower in vitro activity than that of pyrimethamine-sulfadiazine, also has been used in Europe to treat reactivated and congenital infection.[13]

Therapy in Specific Clinical Settings

Acquired Toxoplasmosis

Most immunologically normal patients with the lymphadenopathic form of toxoplasmosis do not require specific treatment. Indications for treatment in these cases are the presence of severe and persistent symptoms and damage to vital organs. Because of the high incidence of severe morbidity and mortality in immunocompromised patients, toxoplasmosis should be treated in this population. Most immunocompromised patients in whom the diagnosis is established ante mortem improve when specific therapy is administered. The major problem lies in establishing the diagnosis early enough to institute treatment.

The optimal duration of specific therapy for toxoplasmosis is unknown. Patients who seem to be immunologically normal but who have severe and persistent symptoms or damage to vital organs should receive specific therapy for 2 to 6 weeks, provided symptoms resolve. In immunocompromised patients, therapy should continue at least 4 to 6 weeks beyond complete resolution of all signs and symptoms of active disease. Careful follow-up of these patients is imperative because relapses may occur and require prompt reinstitution of therapy. In patients with AIDS in whom toxoplasmosis develops, suppressive therapy with pyrimethamine-sulfadiazine, pyrimethamine-clindamycin, or trimethoprim-sulfamethoxazole should be continued for life or until immune reconstitution has been sustained for at least 6 months.

Pregnant Women

Treatment of an acutely infected woman during pregnancy may prevent transmission of the infection to her fetus. The rationale for such treatment is derived from the observation that the incubation period between the onset of maternal infection and acquisition of infection in the fetus may be significant. Data from France,[51,52] where women were treated with spiramycin, and from Austria[9,10] and Germany,[114] where women were treated with pyrimethamine and sulfonamides, indicate that the incidence of congenital infection in the offspring of mothers treated during gestation is at least 50 percent less than that in the offspring of untreated mothers. None of these studies was controlled rigidly. A meta-analysis including 20 cohorts with 1721 infected mothers and 506 infected children suggested that a reduction in the incidence of transmission (odds ratio, 0.48; 95% confidence interval, 0.28 to 0.80) was achieved if therapy was started within 3 weeks of maternal seroconversion.[205] These results combined with the numerous women studied by the group from France (154 untreated and 388 treated patients) strongly suggest that intrauterine treatment does reduce the incidence of transmission of maternal infection to the fetus.[57,197] The meta-analysis failed to show that intrauterine treatment ameliorated the manifestations of congenital infection in children who were born infected, but the large single-site studies from France suggest a benefit. The more recent report of an observational cohort included in the analysis from the European Multicentre Study on Congenital Toxoplasmosis (EMSCOT) showed a significant reduction in serious neurologic sequelae for children with congenital toxoplasmosis who were treated prenatally, with the most significant impact for those women who seroconverted in the first 10 weeks of gestation.[36] Long-term follow-up of young adults who were treated antenatally and postnatally for congenital toxoplasmosis at a single center in France showed remarkably normal quality of life and visual function of the affected individuals.[164] An additional report from a different center in France likewise found minimal disability (74% asymptomatic, 26% with chorioretinitis, and 1 child with serious neurologic involvement) in 107 children treated both prenatally and postnatally.[14]

Spiramycin treatment of pregnant women with recently acquired primary infection should be instituted empirically in the hope of preventing spread of infection to the fetus. When fetal infection has occurred, however, maternal treatment with spiramycin does not seem to alter the evolution and severity of disease in the fetus, which is why evaluation of a potentially exposed fetus by PCR amplification of amniotic fluid permits informed decisions to be made about termination of pregnancy or treatment of the fetus in utero with pyrimethamine-sulfadiazine.

Congenital Infection

Postnatal Treatment. Data regarding the efficacy of postnatal treatment of infants with congenital *Toxoplasma* infection are becoming available.[81,138] The improved outcome reported from several centers in France often includes prenatal treatment as well as postnatal therapy. However, uncontrolled studies in humans and controlled studies in experimental animals[172] have been interpreted as indicating beneficial effects of postnatal treatment on the development of sequelae in symptomatic and asymptomatic infants with congenital *Toxoplasma* infection. The controlled National Collaborative Treatment Trial

is now in progress in Chicago. This study seeks to define optimal therapeutic regimens. Physicians treating patients with congenital *Toxoplasma* infection who are younger than 2.5 months may wish to contact this multidisciplinary group about potential enrollment of their patients in that study (773-834-4152).

Outcomes to date from the National Collaborative Treatment Trial are substantially better for most but not all infants treated from the neonatal period for 12 months with pyrimethamine-sulfadiazine and leucovorin than for historical controls receiving no or short-course therapy.[137] Signs of active infection resolve within weeks of initiation of treatment. In many children, the appearance of brain CT scans has improved remarkably. Cerebral calcifications have diminished in size or resolved in most such treated children.[163] In conjunction with this improvement in brain CT scans, cognitive function has been in the normal range for 69 percent of treated children.[181,201] Overall, 18 (27%) of 66 children in the National Collaborative Treatment Trial have IQ results below 70 compared with 86 (85%) of 101 in the reported literature (see Table 223-1).[54,137]

No significant diminution in cognitive function occurs over time, and most treated children function well in regular school classrooms. Although the number of children compared is limited, for a small subset of these children, measures of cognitive function seem to be less than those for their siblings. No sensorineural hearing loss has been ascribable to congenital toxoplasmosis in treated children.[135,137] Despite the much improved neurologic outlook for most of these children, a subset of children with significant irreversible neurologic damage already present in the perinatal period have manifested profound developmental delay, motor impairment, and seizures. For the most part, these were children with hydrocephalus, high CSF protein concentration, minimal improvement in brain CT scans after shunting, and often substantial delays in shunt placement or needed revision for shunt failure or other intercurrent medical problems.[201] This experience emphasizes the importance of recognizing hydrocephalus and managing it aggressively.

Although treatment during the first year of life arrests all signs of active disease, results in normal cognitive and motor outcomes for most children, and may result in resolution of seizures without recurrence for some treated children, the drugs currently available do not eradicate all cysts containing bradyzoites. In most children, serologic titers of *T. gondii*–specific antibodies rebound in the 3 to 4 months after treatment is discontinued.[137,210]

To date, new retinal lesions have occurred in 17 of 58 children in the National Collaborative Treatment Trial during 3 to 10 years' follow-up after the 1-year course of treatment.[137] These active lesions have responded to brief courses of treatment with pyrimethamine, sulfadiazine, and leucovorin without subsequent loss of visual acuity. Although follow-up durations are shorter, this result contrasts with the almost uniform eventual development of retinal lesions in studies of untreated or briefly treated children.[37,64,112,113,220] We recommend that infected children undergo retinal examination each month for 3 months after discontinuing treatment around their first birthday, then every 3 months until they are old enough to describe visual symptoms accurately, and then every 6 months. In addition, an ophthalmologic evaluation should be performed promptly for any acute visual signs or symptoms that may be related to recrudescence of congenital ocular toxoplasmosis.[146]

Sequential Fetal and Postnatal Treatment. Several studies[42,73,83,90] have described outcomes in patients treated in utero with continuing treatment during the first year of life. As noted earlier, however, pregnancies in which fetuses had obvious manifestations on ultrasound examination and most pregnancies with definite first-trimester infection were terminated.

When the French method of initiating aggressive treatment of fetuses in utero was applied, retinal disease was reported in only 3 of 50 such infants monitored to 2 years of age. This finding contrasts with the presence of retinal or neurologic involvement in 50 percent of asymptomatic newborns detected by serologic screening in Massachusetts[87] and in 75 percent of children whose pediatricians referred them to our National Collaborative Treatment Trial for treatment in the perinatal period.[146] A prospective, carefully controlled study (as part of the National Collaborative Study) is under way to compare directly outcomes in infants identified and treated in utero, as detected by systematic neonatal screening and by pediatricians in the neonatal period and then referred. The outcome of pregnancies with infection acquired in the first trimester after in utero treatment also has been reported to be favorable in another study,[15] in which only pregnancies in which the fetus had hydrocephalus were terminated.

Toxoplasmosis with coexistent HIV infection in children is increasingly rare since the advent of HAART.[62,63,149,162] Most children described with toxoplasmosis and HIV infection have had congenital toxoplasmosis and have been symptomatic. For such children, therapy with pyrimethamine and sulfadiazine plus folinic acid is recommended in the doses described in Table 223-5. Adult and adolescent patients receiving secondary prophylaxis (i.e., long-term maintenance therapy) for acquired toxoplasmic encephalitis are at low risk for recurrence when they have successfully completed initial therapy, remain asymptomatic with regard to signs and symptoms of toxoplasmic encephalitis, and have a sustained increase in $CD4^+$ T lymphocyte counts of more than 200 cells/μL after receiving HAART (e.g., >6 months).

Although the numbers of patients who have been evaluated remain limited and occasional recurrences have been reported, on the basis of these observations and inference from more extensive cumulative data indicating the safety of discontinuing secondary prophylaxis for other opportunistic infections during advanced HIV disease, discontinuation of long-term maintenance therapy among such patients is a reasonable consideration (see http://aidsinfo.nih.gov/guidelines/ for up-to-date Department of Health and Human Services recommendations). The highest risk for relapse seems to occur within the first 6 months of discontinuing secondary prophylaxis. Certain specialists would obtain a magnetic resonance image of the brain as part of their

evaluation to determine whether it is appropriate to discontinue therapy. Zidovudine antagonizes the toxoplasmacidal effect of pyrimethamine and its in vitro synergy with sulfonamide. Whether this effect occurs in vivo is unknown.[119]

Prompt initiation of specific treatment in active ocular toxoplasmosis is mandatory to preserve vision. Inflammatory reactions in the vitreous frequently are a major pathogenetic phenomenon in patients with active disease, and in such cases, administration of corticosteroids in addition to specific anti-*Toxoplasma* therapy is recommended strongly.[190] Their use also is recommended for cases of retinochoroiditis involving the macula, maculopapillary bundle, or optic nerve. The initial daily dosage of prednisone is 1 mg/kg orally to a maximum of 75 mg in 24 hours. The equivalent dosage of another corticosteroid may be given. The dosage of corticosteroid may be reduced gradually when the lesion appears to be well demarcated and pigmentation has begun. Some physicians have administered systemic or intraocular clindamycin to treat patients in whom the use of corticosteroids and pyrimethamine plus sulfadiazine has failed[202]; its efficacy has not been proved in humans.

PREVENTION

Congenital infection may be avoided by preventing primary *Toxoplasma* infection during pregnancy.[67,134,219,224] The responsibility of all physicians caring for pregnant women at risk is to inform them of specific hygienic measures (Table 223-6) for avoiding *Toxoplasma* infection. Similar measures are useful for prevention of acquired infection in other settings as well. The effectiveness of a 10-minute education program, offered as part of prenatal care, to reduce the risk of acquiring *Toxoplasma* infection by modifying the behavior of pregnant women with regard to cats, food, and personal hygiene has been shown.[28] Pamphlets that describe methods to prevent toxoplasmosis in pregnant women are available from the March of Dimes (312-435-4007), from Abbott Diagnostics (800-323-9100), and on the Internet (www.cdc.gov/parasites/toxoplasmosis/resources/ToxoWomen_2.2003.pdf).

When primary maternal infection has occurred, several problems are inherent in the secondary prevention of congenital toxoplasmosis by therapeutic abortion or by treatment of the pregnant woman.[30] Because 80 to 90 percent of women with primary *Toxoplasma* infection are asymptomatic, most primary infections are overlooked, unless sequential serologic testing is performed routinely in pregnant women. The cost-effectiveness of routine screening in the prevention of congenital toxoplasmosis is clear in some European countries where screening is mandated by law.[51] In countries with a lower incidence, cost-efficiency has not been proved.[79,82,178] A recent analysis of the cost of a universal screening program for pregnant women in the United States modeled after the French approach suggests cost savings for the U.S. population even with current levels of congenital infection.[110,179,198] In the absence of national guidelines, physicians may choose to screen patients on an individual basis.[218] If screening is undertaken, a reliable serologic test for IgG antibodies (see section on laboratory diagnosis) should be performed before conception occurs or as soon as possible thereafter and then repeated every 2 to 3 months until the time of delivery. Serologic test results that suggest the acquisition of primary infection during pregnancy should be confirmed by a reference laboratory. Decisions about treatment or therapeutic abortion should be based on a consideration of whether the fetus is infected or affected, as determined by amniocentesis and ultrasonography.

TABLE 223-6 **Prevention of Toxoplasma Infection**

Prevention of Acquired Infection (Primary Prevention)
Cook meat to medium (66°C [150°F]), smoke it, or cure it in brine.
Wash fruits and vegetables before consumption.
Avoid touching mucous membranes of the mouth and eyes while handling uncooked meat or unwashed fruits or vegetables.
Wash hands and kitchen surfaces thoroughly after contact with raw meat or unwashed fruits or vegetables.
Prevent access of flies, cockroaches, and other coprophagous insects to fruits and vegetables.
Avoid contact with materials that potentially are contaminated with cat feces, such as cat litter boxes, or wear gloves when handling such materials and when gardening.
Disinfect cat litter boxes for 5 minutes with nearly boiling water.
Prevention of Congenital Infection (Secondary Prevention)
Identify women at risk by serologic testing.
Treatment during pregnancy results in an approximately 50% reduction in the incidence of infection in infants.
Therapeutic abortion prevents birth of an infected infant—consider only for women who acquire infection in the first or second trimester.

THE ORGANISM

Pneumocystis was originally identified in 1909 by Chagas, who believed it was a form of *Trypanosoma cruzi*.[9] It is now known to be a unique and ubiquitous pathogen of mammals. The first description of *Pneumocystis* infecting a human was reported in 1942.[76] The taxonomic placement of *Pneumocystis* has been difficult and varied over time. The organism has features of both protozoa and fungi. Protozoan features include morphology with three distinct forms, termed *cyst*, *sporozoite*, and *trophozoite*, sensitivity to antimicrobial agents with activity against protozoal organisms, and resistance to most antifungal drugs. Fungal features include the structure of the cyst wall, which contains chitin and β-1,3-glucan, and its genetic structure is more typical of that of fungi.[20,21]

Because *Pneumocystis* cannot be maintained in culture, definitive knowledge of its life cycle is limited. The thick-walled cyst is 5 to 8 μm in diameter and contains up to 8 μm sporozoites (or intracystic bodies), which on leaving the cyst become trophozoites (or tropic forms) varying in size from 1 to 4 μm (Fig. 224-1). There is some evidence for a sexual cycle in *Pneumocystis* based largely on the presence of homologs of genes involved in sexual cycles in fungi.

Pneumocystis strains or species have the remarkable biologic feature of only being able to infect a single mammalian species[26]; for example, organisms isolated from mice are incapable of infecting other mammals, even one as closely related as a rat. This restricted transmission is consistent with studies demonstrating unique phenotypes and genotypes of *Pneumocystis* isolated from each mammalian host studied to date.[28,30,58,69,84] The obvious implication of this biologic property is that the source of *Pneumocystis* causing PCP in humans must be other humans.

The host species specificity and restricted transmission have led to discussions regarding whether these features represent distinct species of *Pneumocystis*. Efforts have been made to adopt new nomenclature for *Pneumocystis*, primarily to distinguish between strains derived from humans and strains from lower mammals. In 1976, Frenkel suggested *P. jiroveci* n. sp. for isolates from humans.[23] During the ensuing three decades this term was not used. In 1988, Hughes and Gigliotti[37] proposed a nomenclature merely designating the host from which the organism was obtained (e.g., *P. carinii*, *humanus; P. carinii*, *rattus*). In 1994, Stringer and the *Pneumocystis* Workshop[70] used DNA sequence data to employ a "special forms" designation (e.g., *P. carinii* f. sp *hominis*). A subsequent system put forth in 2002 by Stringer and colleagues[71] is currently used by some investigators and designates the human form as *P. jiroveci* Frenkel. *P. jiroveci* is being increasingly used to designate *Pneumocystis* that infects humans. However, because issues have been raised regarding this new nomenclature, some authors use only the genus name when describing this organism.[25,32,43,71]

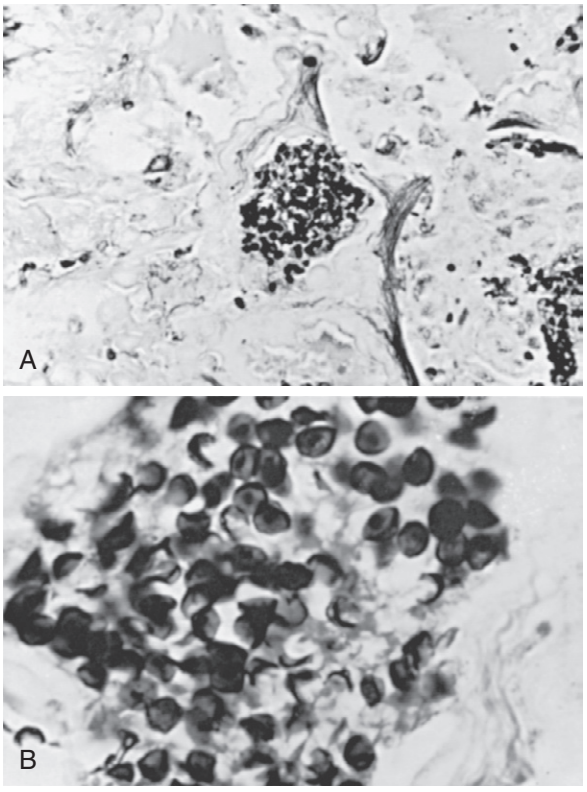

FIGURE 224-1 ■ Typical cyst forms shown by Gomori silver methenamine stain of lung tissue obtained by open lung biopsy from a 20-month-old child with severe combined immunodeficiency disease (**A,** 100×; **B,** 100×).

TRANSMISSION AND EPIDEMIOLOGY

Transmission

Pneumocystis is spread by the airborne route.[33] *Pneumocystis* has been isolated from a wide variety of animal species from all over the world. Because *Pneumocystis* organisms isolated from different mammalian hosts are morphologically quite similar, it was initially thought that PCP in humans was a zoonotic infection stemming from contact with infected animals. As noted earlier, it is now clear that transmission between two different mammalian species is highly unlikely. Longitudinal serologic studies starting just after birth demonstrate that most children are infected with *Pneumocystis* by 2 years of age.[77] These serologic data are substantiated by the finding of *Pneumocystis* in the lungs of many infants who have died of sudden infant death syndrome.[54,78] Infection of a normal host early in life could result in the establishment of a latent infection, as happens in the case of tuberculosis. This was believed to be the case with *Pneumocystis* where infection in the immunocompromised host was postulated to be the result of reactivation of a latent *Pneumocystis* infection.[13] However, under controlled experimental conditions, normal mice were shown to control *Pneumocystis* after infection in a typical pattern of infection, immune response, and resolution of infection.[3] Furthermore, latent infection does not occur after immune-mediated resolution of infection.[10] Once infected, but before

resolution of infection, immunologically normal mice can transmit *Pneumocystis* to another mouse.[29] If the recipient mouse is normal, a subclinical infection occurs. This cycle, if repeated, would serve to maintain *Pneumocystis* in the population. If instead the recipient mouse is immunocompromised, then full PCP results.

By using information gained from animal models and observational studies it is possible to propose a likely transmission cycle for *Pneumocystis*. Seronegative infants who are continuously introduced into the population present a large pool of susceptible humans that become transiently infected. Infection can be either asymptomatic or mildly symptomatic.[77] In either case, the infection is transmissible. Continued passage from normal host to normal host would serve as a reservoir of *Pneumocystis* that when transmitted to an immunocompromised individual results in life-threatening PCP. Consistent with this model, molecular studies suggest that a second case of PCP occurring more than 6 months after the first episode is most likely the result of reinfection with a new strain of *Pneumocystis*.[45] It is not known whether subclinical reinfection of adults can serve as another reservoir of *Pneumocystis*, but the finding of microscopically visible organisms rarely has been documented in adults.

Pneumocystis Pneumonia and AIDS

AIDS was brought to the attention of the medical community in the United States as a result of a small cluster of cases of PCP in previously healthy young men,[8] and PCP remains the most common AIDS-defining illness. It was reported in 39 percent of 2786 pediatric AIDS patients reported to the Centers for Disease Control and Prevention (CDC) through 1990 and in 75 percent of untreated adults with AIDS, and more than half of adults dying with AIDS have had at least one episode of PCP.[43,67] The key determinant in host defense against PCP is the $CD4^+$ T cell. Although the precise role of $CD4^+$ T cells in protection against PCP has not been defined, it is clear that any condition that interferes with $CD4^+$ T-cell number or function puts the patient at risk for developing PCP. Because the pathogenesis of AIDS involves the destruction of $CD4^+$ T cells, it is easy to identify at-risk patients simply by checking $CD4^+$ T-cell counts. Adults whose $CD4^+$ T-cell counts fall below 200/μL are at high risk to develop PCP. The determination of risk of PCP in children with AIDS is based on age because $CD4^+$ T-cell counts are very high at birth, fall rapidly during the first year of life, and then fall more slowly to reach adult levels around 6 years of age. Thus, children with AIDS are at high risk to develop PCP if they are younger than 1 year of age with $CD4^+$ T-cell counts less than 1500/μL; 1 to 5 years of age with counts less than 500/μL; and older than 5 years of age with $CD4^+$ T-cell counts less than 200/μL.

Pneumocystis Pneumonia Not Associated with AIDS

The other large group of patients at risk for PCP is those with congenital immunodeficiencies involving T- and B-cell function and those with medical conditions requiring immunosuppressive therapy, such as malignancies. For this latter group, it is important to remember that it is generally the therapy and not the underlying disease that puts the patient at risk to develop PCP. This is clearly demonstrated in children with acute lymphocytic leukemia when those receiving one, two, or three chemotherapeutic agents had an incidence of PCP between 2 and 5 percent whereas in those receiving four drugs the incidence was 22 percent.[29] Likewise, the addition of irradiation to a three-drug chemotherapeutic regimen increased the incidence of PCP to as high as 35 percent.[35] Thus, it is important to keep in mind that as therapies change, so, too, does the risk for developing PCP. For example, PCP was rarely seen in patients with Crohn disease receiving conventional immunosuppressive therapy. However, PCP is now a well-recognized complication of Crohn disease since the addition of anti-tumor necrosis factor (TNF) therapy to the treatment regimen.[44]

The incidence of PCP seems to be increasing, possibly owing to the increasing use of biologic response modifiers, such as anti-TNF agents, and newer more potent immunosuppressive drugs. Reports from cancer centers show that the incidence or prevalence or both of PCP has increased in this population.[58,85] Similar increases are reported among patients receiving organ transplants, those with autoimmune diseases, and those who have had a bone marrow transplant.[4,57,75]

In contrast to patients with AIDS, in which there is consensus on the guidelines for starting PCP prophylaxis, the risk for developing non–AIDS-associated PCP can be more difficult to predict. This is because the immunosuppressive regimen affects not only cell number but also cell function. Thus, a patient on chemotherapy may have a $CD4^+$ T-cell count above the risk threshold seen in AIDS patients, but if function is suppressed then the risk for PCP increases. Because T-cell function is not routinely measured in clinical laboratories, physicians must rely on cumulative clinical experience when judging the need for PCP prophylaxis.

IMMUNOPATHOGENESIS

Pneumocystis is the classic opportunistic pathogen: it is incapable of producing overt pneumonia in the immunologically normal host, yet in the immunocompromised host PCP is universally fatal if untreated. Even with treatment the mortality is high, ranging from 5 to 25 percent, depending on the patient population.

The occurrence of PCP in patients with AIDS and pure T-cell deficiency disease provides indirect evidence of the potential importance of cellular immunity in protecting the host against this opportunist. Direct evidence for the necessity of $CD4^+$ T cells comes from mouse studies showing that depletion of this cell population renders the mouse susceptible to PCP. Less well appreciated is the evidence for the importance of humoral immunity in protection against *Pneumocystis*. For example, PCP occurs in patients with agammaglobulinemia or hyper-IgM syndrome and mice with a variety of genetically engineered defects in antibody response pathways have been demonstrated to be susceptible to PCP.

The host response to *Pneumocystis* is likely the critical determinant of the severity of lung injury occurring as a result of PCP.[27] Three clinical observations support the importance of the inflammatory response in the outcome of PCP: (1) neutrophil number, but not organism counts, in lung secretions correlates with higher morbidity and mortality[50]; (2) the differential in mortality between AIDS-related and non–AIDS-related PCP[51]; and (3) the ability of PCP to trigger the immune reconstitution inflammatory syndrome (IRIS).[56]

In recent years, the application of molecular technology has provided a vast amount of information to aid in understanding the immunopathogenesis of PCP.[27] When *Pneumocystis* reaches the lungs of a normal host by the airborne route, the organism elicits what we have termed a *balanced immune response* and the subject remains asymptomatic or mildly symptomatic while the infection is cleared. Alternatively, if the host is severely immunocompromised owing to insufficient $CD4^+$ cells, a life-threatening pneumonitis develops, driven by $CD8^+$ T cells. Because $CD8^+$ T cells are a critical determinant of the lung injury, without controlling organism burden, we have termed this response *ineffective inflammation*. Finally, in the setting of return of $CD4^+$ T cells, such as after institution of treatment for human immunodeficiency virus (HIV) infection or during engraftment after bone marrow transplantation, one may see an exaggerated but effective response, as seen in IRIS, that clears the *Pneumocystis* but at the expense of significant lung injury.

Alveolar macrophages play a critical role in pulmonary host defense and contribute to both innate and adaptive immune responses. Alveolar macrophages have long been thought to serve as the effector cell for clearing *Pneumocystis* organisms from the lung, but these cells are not capable of controlling *Pneumocystis* infection in hosts with impaired $CD4^+$ T-cell function. A recent study utilizing an animal model of PCP has demonstrated that macrophage phagocytosis is the effector mechanism for the $CD4^+$ T-cell–mediated clearance of *Pneumocystis* organisms from the lung, indicating that the adaptive immune response must direct the macrophage-mediated clearance of this fungal pathogen.[80] In addition to host defense, macrophages also likely contribute to the immunopathogenesis of PCP. Macrophages are significant sources of proinflammatory cytokines, including TNF-α and interleukin-1 (IL-1), and *Pneumocystis* β-glucan is a potent stimulator of the alveolar macrophage cytokine response.[47] Therefore, in addition to their function in host defense, alveolar macrophages may also contribute to PCP-related lung injury through elaboration of inflammatory mediators.

The proinflammatory cytokines TNF-α and IL-1 are required for host defense against *Pneumocystis* infection[11,12] but also contribute to the immunopathology associated with PCP. These cytokines, acting through chemokine signals, promote neutrophil, lymphocyte, and monocyte recruitment to the lung, which may cause alveolar damage and diminished gas exchange, resulting in respiratory failure. Importantly, mice lacking TNF receptors are partially protected from PCP-related respiratory impairment and weight loss.[83] Other cytokines associated with T-helper cell type 1, 2, or 17 responses may also modulate host defense and PCP-related immunopathogenesis by regulating alveolar macrophage phenotype and activation state, but these issues need further clarification.

Surfactant phospholipids and apoproteins are critical to lung function and are adversely affected by *Pneumocystis* infection. Patients with PCP display dramatic alterations in surfactant function and composition,[65] which is likely an important determinant of disease severity. In vitro studies have determined that *Pneumocystis* organisms interact directly with pulmonary surfactant to reduce its surface tension–lowering properties.[81] Furthermore, studies in animal models have found that *Pneumocystis*-driven inflammation also contributes to surfactant dysfunction in the setting of PCP.[5,82] Anecdotal reports describe some benefit from the administration of exogenous surfactant to patients with PCP.[15]

PATHOLOGY

The pathologic findings of *Pneumocystis* infections are, with rare exceptions, limited to the lungs. Rarely, *Pneumocystis* organisms have been detected in the lymph nodes, spleen, liver, retina, bone marrow, gastrointestinal tract, pancreas, heart, adrenals, and peripheral blood.[73]

In the infantile "epidemic" form of disease, essentially all alveoli contain large numbers of organisms. Extensive interstitial plasma cell infiltrates distend the alveolar walls 5 to 20 times over their normal thickness, and almost no intra-alveolar fibrinous exudate is noted.[31]

The progression of disease in childhood and adult forms of PCP can be divided into three pathologic stages.[31,61] An initial stage is characterized by the presence of cysts and trophozoites attached, possibly by fibronectin, to the alveolar walls.[60] No septal inflammatory or cellular response is evident, and no clinical disease is associated with this stage. A second stage, which may or may not be associated with clinical signs and symptoms, is characterized by desquamation of alveolar cells and an increase in the number of cysts within alveolar macrophages. TNF may be a major mediator involved in the killing of *Pneumocystis* by activated alveolar macrophages and may be induced by oxidative stress in the alveoli.[59] The final stage is typified by extensive reactive and desquamative alveolitis manifested by marked cytoplasmic vacuolization of macrophages, mononuclear and plasma cell infiltrates within alveolar septa, and clusters of organisms located predominantly within macrophages in the lumen of alveoli. The histopathology of this final stage definitely is associated with clinical manifestations of pneumonitis.[61]

CLINICAL MANIFESTATIONS

Hypoxia is the hallmark of PCP. The natural course of *Pneumocystis* infection varies greatly and depends primarily on the status of host defenses in individual patients. The onset may be insidious, with a clinical course of 3 weeks or more, or be fulminant and rapidly progressive over a few days. For example, AIDS patients are probably

more immunocompromised than oncology patients at the point in time when they develop PCP, as evidenced by typically higher organism burdens, yet AIDS patients are more likely to have a longer history of symptoms and a lower mortality rate than non-AIDS patients.[51,72]

Symptoms in immunosuppressed children or adults without AIDS may be more abrupt in onset and rapidly progressive, but, even with these patients, the course varies greatly.[6,41] The mortality rate approaches 100 percent in untreated cases. In cases in children and adults, in contrast to infantile cases, fever generally is present and of high grade. It often precedes the onset of nonproductive cough, tachypnea, and severe dyspnea. Fever, tachypnea, and the radiographic appearance of pulmonary infiltrates, in that sequence, 1 to 21 days before diagnosis was established, occurred in a group of children with malignancies. The time of onset of clinical disease in non-AIDS, high-risk patients is unpredictable, but disease often occurs after discontinuance or a reduction in the dose of corticosteroid therapy.[6] Patients with severe combined immunodeficiency disease who receive a bone marrow transplant subsequently may contract fulminant PCP when apparent immunologic reconstitution has occurred.[6] These observations support the hypothesis that the clinical features early in the course of PCP are dependent to a large extent on the patient's ability to mount an inflammatory response.

Infants and children with AIDS may have a more insidious onset of PCP and therefore may come to medical attention later than non-AIDS patients. In this scenario, the patient is usually acutely ill with fever, cough, dyspnea, tachypnea, and an alveolar-arterial oxygen gradient greater than 30 mm Hg at the time of diagnosis.[14]

In children and adults with and without AIDS, physical examination at the time of initial evaluation may reveal tachypnea; nasal flaring; and intercostal, subcostal, or suprasternal retractions. An ashen color or cyanosis may be present or may develop rapidly. Auscultation of the chest frequently is characterized by a conspicuous absence of adventitious sounds despite the presence of rapid (80 to 100 breaths/min), shallow respirations. Scattered rales, rhonchi, or wheezes most often are detected later in the clinical course as resolution occurs. Aside from variable elevation in temperature, few other physical abnormalities are noted except those referable to pulmonary disease or secondary to the patient's underlying disease or treatment.[6,41]

Various radiographic abnormalities have been observed in documented cases of isolated PCP.[19,22] These variations result partly from observations at different stages in the course of disease. Bilateral diffuse parenchymal infiltrates (Fig. 224-2) occur most commonly, but no pattern is sufficiently specific either to exclude or to confirm a diagnosis of PCP. Although initially a reticulogranular interstitial process, *Pneumocystis* pneumonitis progresses to a predominantly alveolar process with coalescence and air bronchogram formation. Late in the course of the disease, lung fields may opacify completely. Unusual radiographic findings, including an asymmetric distribution, consolidated lobar infiltrates, pneumothorax and pneumomediastinum, localized parenchymal nodular densities, and pleural effusion, have been documented.[19] During treatment, radiographs show gradual clearing after a variable latent period, during which they may appear worse. Residual interstitial fibrosis occurs in a small percentage of patients.

DIAGNOSIS

The clinical features associated with PCP are not sufficiently specific to differentiate it from other opportunistic pulmonary infections. Mixed infections with viral, bacterial, fungal, or parasitic agents have been documented along with *Pneumocystis*. Implicit in these observations is the importance and urgency of establishing a definitive diagnosis before the institution of specific

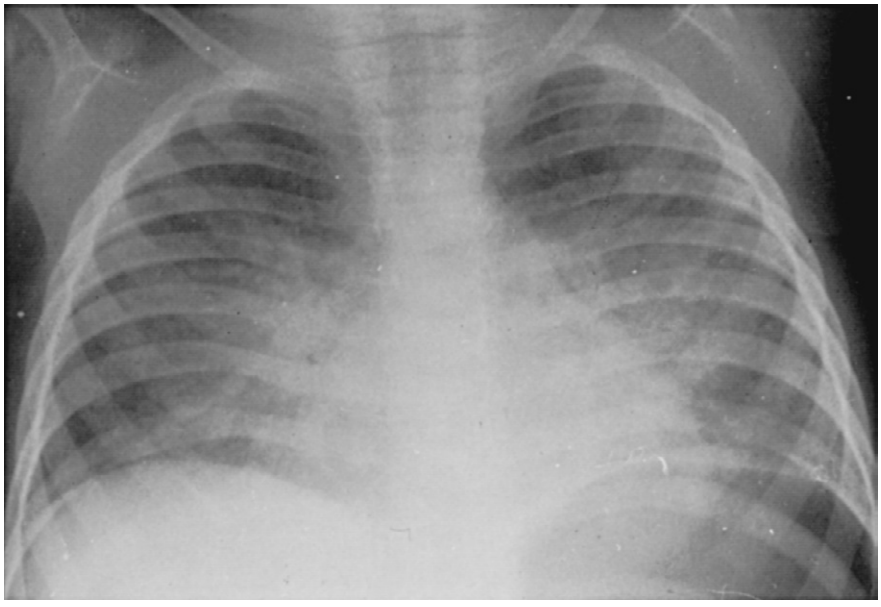

FIGURE 224-2 ■ Typical diffuse interstitial infiltrates seen in a 20-month-old child with severe combined immunodeficiency disease at the time of evaluation for clinical *Pneumocystis carinii* pneumonitis.

therapy. An etiologic diagnosis can be ascertained only by the demonstration of *Pneumocystis* organisms in lung tissue or respiratory secretions.

Numerous techniques have been used to obtain suitable material for diagnostic purposes. Specimens obtained by noninvasive methods, especially from induced sputum or tracheal aspirate, have been used to reveal *Pneumocystis*, and the sensitivity of these methods is 50 to 60 percent. Bronchoalveolar lavage is quite reliable with a sensitivity of 90 to 95 percent.[16] Other methods of obtaining a specimen, such as endobronchial brush biopsy, transbronchial lung biopsy, or percutaneous needle aspiration, have been used successfully to establish a diagnosis of PCP but are not commonly used since the advent of bronchoalveolar lavage.

If PCP remains a possibility after using the just-noted diagnostic methods, one should proceed to an invasive technique such as open-lung biopsy. Open-lung biopsy provides the most dependable specimen from which identification of the organism and the extent of the infection can be ascertained.[1] The chief disadvantage is the need for general anesthesia.

For diagnostic purposes, the methenamine silver nitrate method of Gomori and the less widely used, but more rapid, toluidine blue O and calcofluor white stains are most useful for showing cyst forms in tissue sections, aspirates, or imprints. For more detailed morphologic study of intracystic sporozoites and trophozoites, polychrome stains, including Giemsa, Wright, Gram, and methylene blue stains, are more suitable. In tissue sections, the Gomori stain in combination with hematoxylin and eosin staining allows study of the organism and host tissue. A direct immunofluorescent monoclonal antibody technique has become commercially available.[62] Serologic methods are not useful for diagnostic purposes.

There are a large number of studies describing detection of *Pneumocystis* DNA by polymerase chain reaction. Although this has proved to be a valuable laboratory technique, it has had limited use in clinical situations. Reported sensitivities are excellent, but specificities can be less than 85 to 90 percent.[2,74] At this time, polymerase chain reaction remains a research tool and is not widely used in general clinical practice.

Hematologic studies are of no diagnostic value, primarily because of baseline abnormalities reflecting the underlying disease of affected patients. Eosinophilia has been reported in isolated cases but usually is not present. Depressed serum total protein and albumin values frequently are noted because of the poor nutritional status of representative patients. Lactate dehydrogenase activity is increased, but it is not a specific marker for PCP and is of little diagnostic benefit.[79]

PROGNOSIS

Before the availability of specific therapeutic agents, the overall prognosis of patients with PCP was poor. Despite supportive care, almost 100 percent of infected patients with underlying neoplastic or immunodeficiency disorders died, whereas approximately 50 percent of infants in the European epidemics died as a result of this pulmonary infection. With modern medical management, the prognosis for patients with PCP depends to some extent on the underlying risk factor for PCP. For example, the mortality for PCP in cancer patients (25% to 40%) is four to five times higher than for those with AIDS (5% to 10%).[51] Patients who require mechanical ventilation have mortality rates in excess of 60 to 70 percent. A similar high mortality is seen in infants with PCP whose disease progresses and who then require mechanical ventilation.[66]

TREATMENT

Trimethoprim-sulfamethoxazole is the drug of choice for both the treatment and prevention of PCP.[36,46] A minimum of 2 weeks of therapy is recommended for non-AIDS patients; 3 weeks may be optimal for patients with AIDS. The CDC, the National Institutes of Health, and the Infectious Diseases Society of America have provided consensus guidelines for the treatment and prevention of PCP in immunosuppressed patients (Table 224-1).[7] Atovaquone, a hydroxynaphthoquinone approved by the U.S. Food and Drug Administration, is effective and has few side effects (rash, nausea, and diarrhea). It can be administered only by the oral route.[40] The sulfone dapsone has been evaluated in children[24] and may be used alone but is synergistic with trimethoprim[49] against *P. jiroveci*. Dapsone may cause rashes, neutropenia, thrombocytopenia, anemia, and methemoglobinemia. Clindamycin plus primaquine has also been used.[64]

Some studies in adults with AIDS and PCP suggest that the administration of corticosteroids early in the course of moderately severe pneumonitis reduces the occurrence of respiratory failure and improves oxygenation.[55] Other studies show no benefit from corticosteroids.[18] Limited studies of this supportive therapy have been reported to increase survival in children.[68] When used, a reasonable approach seems to be to withdraw corticosteroid therapy as soon as pulmonary function has become stabilized.

PREVENTION

PCP can be prevented in more than 95 percent of patients at high risk for acquiring the disease.[39,42] Patients in high-risk groups, such as patients with cancer, acquired and congenital immunodeficiency disorders, and organ or bone marrow transplants or those receiving intensive immunosuppressive therapy, should be placed on a chemoprophylaxis regimen throughout the risk period (see Table 224-1).

Because of the high risk for acquiring PCP during the first year of life, often before HIV infection is recognized, PCP prophylaxis should be initiated at 4 to 6 weeks of age in all infants born of HIV-infected women, regardless of $CD4^+$ lymphocyte cell counts. The use of chemoprophylaxis in this age group has been highly effective in HIV-infected infants.[63] When infants are shown not to be infected with HIV, prophylaxis may be discontinued. HIV-infected infants and infants with undetermined

TABLE 224-1 **Dosing Recommendations for the Prevention and Treatment of *Pneumocystis* Pneumonia**

Indication	First Choice	Alternative	Comments/Special Issues
Primary prophylaxis	Trimethoprim 5 mg/kg with sulfamethoxazole 25 mg/kg (TMP-SMX) daily generally divided into two doses. The total daily dose should not exceed 1600 mg SMX and 320 mg TMP. Several dosing schemes have been used successfully: given 3 days per week on consecutive days or on alternate days; given 2 days per week on consecutive days or on alternate days; or given every day.	Dapsone (children ≥1 mo), 2 mg/kg (maximum, 100 mg) orally daily or 4 mg/kg (maximum, 200 mg) orally weekly. Atovaquone (children aged 1 to 3 mo and >24 mo, 30 mg/kg orally daily; children aged 4 to 24 mo, 45 mg/kg orally daily) Aerosolized pentamidine (children aged ≥5 yr), 300 mg every month via Respirgard II nebulizer	*Primary prophylaxis indicated for:* All HIV-infected or HIV-indeterminate infants aged 4-6 wk to 12 mo regardless of CD4 count/percentage; HIV-infected children aged 1 to 5 yr with CD4 count <500 cells/mm^3 or CD4 percentage <15%; HIV-infected children aged 6 to 12 yr with CD4 count <200 cells/mm^3 or CD4 percentage <15%. *Criteria for discontinuing primary prophylaxis:* Do not discontinue in children aged <1 yr. After ≥6 mo of HAART and: Age 1 to 5 yr, CD4 percentage or count is ≥15% or ≥500 cells/mm^3 for >3 consecutive months *or* Age ≥6 yr, CD4 percentage or count is ≥15% or ≥200 cells/mm^3 for >3 consecutive months *Criteria for restarting primary prophylaxis:* Age 1 to 5 yr with CD4 percentage <15% or count <500 cells/mm^3 Age ≥6 yr with CD4 percentage <15% or count <200 cells/mm^3
Secondary prophylaxis (prior *Pneumocystis* pneumonia [PCP])	Same as for primary prophylaxis	Same as for primary prophylaxis	Secondary prophylaxis indicated for children with prior episode of PCP. *Criteria for discontinuing secondary prophylaxis:* same as for primary prophylaxis. *Criteria for restarting secondary prophylaxis:* same as for primary prophylaxis.
Treatment	TMP-SMX 15–20 mg/kg TMP *plus* 75-100 mg/kg SMX daily given IV orally in three to four divided doses given for 21 days (followed by prophylaxis dosing)	*If TMP-SMX intolerant or clinical treatment failure after 5 to 7 days of TMP-SMX therapy):* Pentamidine 4 mg/kg IV once daily is first choice alternative regimen (pentamidine may be changed to atovaquone after 7 to 10 days IV therapy) Atovaquone 30-40 mg/kg (maximum, 1500 mg/day) orally in two divided doses with food for patients from birth to 3 mo and ≥24 mo. For infants from 3 to 24 mo, an increased dose of 45 mg/kg daily in two divided doses with food is needed.	After acute pneumonitis resolved in mild-moderate disease, IV TMP-SMX may be changed to oral dosing. Dapsone 2 mg/kg orally once daily (maximum, 100 mg/day) *plus* trimethoprim 15 mg/kg/day orally divided into three doses has been used in adults but data in children are limited. Primaquine base 0.3 mg/kg orally once daily (maximum, 30 mg/day) *plus* clindamycin 10 mg/kg IV or by mouth (maximum 600 mg given IV and 300 to 450 mg given orally) every 6 hr has been used in adults, but data in children are not available. *Indications for corticosteroids:* Pao_2 <70 mm Hg at room air or alveolar-arterial oxygen gradient >35 mm Hg Prednisone dose: 1 mg/kg orally twice daily for 5 days, then 0.5-1 mg/kg orally twice daily for 5 days, then 0.5 mg/kg orally once daily for days 11 to 21. Chronic suppressive therapy (secondary prophylaxis) with TMP/SMX is recommended in children and adults after initial therapy.

status should be continued on prophylaxis during the first year of life. At 1 year of age and subsequently, the use of chemoprophylaxis is based on the $CD4^+$ lymphocyte count and other AIDS-defining features.

Trimethoprim-sulfamethoxazole given 3 days per week is the preferred drug for chemoprophylaxis. For patients unable to take trimethoprim-sulfamethoxazole, dapsone 2 mg/kg/day or 4 mg/kg/wk is suggested.[24] Studies in adults show that daily doses of dapsone[53] or one dose of dapsone per week[38] is effective prophylaxis.[52] An alternative to dapsone is aerosolized pentamidine 300 mg monthly via Respirgard II inhaler.[48] The dosage for aerosolized pentamidine is the same as the dosage for adults.[48] Atovaquone has been shown to be effective and safe in children.[17] A controlled study compared prophylaxis with atovaquone and azithromycin with trimethoprim-sulfamethoxazole in 366 high-risk, HIV-infected children.[34] The regimens were similar in effectiveness in prevention of bacterial infections, and PCP occurred with equal frequency.

Studies in adults and children show that PCP prophylaxis can be discontinued safely in patients responding to highly active antiretroviral therapy with a sustained increase in $CD4^+$ T lymphocytes to levels above the risk threshold for PCP (see Table 224-1).

Patients are protected from pneumonitis only while receiving chemoprophylaxis and become susceptible again when use of the drugs is discontinued. No vaccine is available.

SUBSECTION 2 *NEMATODES*

CHAPTER 225

Parasitic Nematode Infections

Peter J. Hotez

INTESTINAL NEMATODES

The three major intestinal nematodes of children, *Ascaris lumbricoides*, *Trichuris trichiura*, and the hookworms, together have a substantial impact on the health and well-being of children living in less-developed nations of the world.[3] This "unholy trinity" of soil-transmitted helminths (STHs), or "geohelminths," deprives hundreds of millions of young children of their full intellectual and growth potential. Some estimates suggest that 2 billion people are infected with STHs, 300 million of whom have severe morbidity. An estimated 400 million schoolchildren are infected with STHs, although these estimates are undergoing revision through the activities of a new global helminth atlas.[4] Building on studies from the early part of the 20th century,[21,22] extensive new data from many different geographic regions confirm that chronic intestinal nematode infections acquired during childhood

suppress cognitive and intellectual development[6,19,22] and impair physical growth and fitness.[7,24-26] Through these mechanisms the STH infections can actually cause poverty in the world's low- and middle-income countries.[11] Because many of these detrimental effects are reversible with the use of anthelmintic drugs to eliminate nematodes from the intestinal tract,[25,26] several investigators and international relief agencies have advocated the administration of benzimidazole anthelmintics (sometimes known as "deworming") as a cornerstone of public health programs directed at school-aged children.[3,5,20]

A 2001 World Health Assembly resolution urges its member states to "deworm" at least 75 percent and up to 100 percent of school-aged children at risk for acquiring STH infections through programs of mass drug administration (MDA).* Additional studies also point to the benefits of deworming preschool-aged children.[1] Globally, efforts are underway to link deworming for STH infections with MDA for other neglected tropical diseases, including lymphatic filariasis, onchocerciasis, and trachoma,[8,11,15] as well as linking deworming to the control of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), malaria, and tuberculosis.[13]

In some highly endemic areas, reinfection with *A. lumbricoides*, *T. trichiura*, and hookworms occurs within 6 months of receiving anthelmintic treatment.[2] Therefore, MDA is not always a practical means of control, unless the drugs are used frequently. Newer information suggests that the efficacy of single-dose anthelmintic drugs used for MDA may not be as high as believed previously.[17] Concern about the potential for emerging anthelmintic drug resistance also exists. Some researchers have pointed to the use of genetically engineered anthelmintic vaccines as one possible solution to the problem of worm reinfection and disease during childhood.[10] Still another public health concern about the chronic effects of STH infections is new evidence suggesting that they may promote the susceptibility to, or worsen the severity of, malaria and HIV infection/AIDS.[14] Interest has developed in examining the impact of large-scale deworming on these killer diseases.[13,18] New information also indicates the potential impact of parasitic infections, including STH infections in developed countries such as the United States and Europe.[8,12,23]

In addition to the chronic effects seen when children harbor numerous intestinal nematodes are the increasingly recognized unique neonatal and infantile syndromes that new information indicates may result from vertical transmission of the infective stages of some intestinal nematodes, probably in colostrum and breast milk.[3,9] The best documented example of vertical transmission in infants results in the "swollen belly syndrome" caused by *Strongyloides fuelleborni kellyi*, although other perinatal nematode infections probably also occur (see later discussion). Finally, children experience significant morbidity during zoonotic transmission of the infective stages of intestinal nematodes of companion animals such as dogs and cats. The resultant aberrant migration of these foreign nematode larvae (visceral larva migrans) has become a major pediatric public health problem in large urban areas of the United States and Europe.[12,16]

ASCARIS LUMBRICOIDES

Ascariasis is one of the most prevalent infections in the world,[33,34] with an estimated 800 million cases in the developing world.[3] Accurate determinations based on 1,477,742 fecal examinations conducted during the 1990s indicated that more than 500 million cases of ascariasis occur in China alone[49]; however, revised estimates now suggest that those numbers have declined significantly, especially in economically developed regions of eastern China.[3] Currently, the greatest number of cases of ascariasis occur in Southeast Asia and the Indian subcontinent and sub-Saharan Africa.[3] Surveys conducted in the rural southern communities of the United States during the 1970s indicated that the prevalence of ascariasis was 20 to 67 percent.[28] Those rates most likely have declined significantly over the past few decades, however.[8,23]

Ascaris infection, when relatively light, is usually not apparent until the patient passes a worm through the rectum. In heavy infections, constitutional symptoms may occur during the early phase and intestinal malabsorption and obstruction may occur in the later phase. The infection is acquired by ingestion of the infective eggs, which hatch in the upper part of the small intestine and free the larvae. The larvae penetrate the intestinal wall, reach venules or lymphatics, and pass through the portal circulation to the liver, the right ventricle, and the lungs.

In the lungs, the larvae break out of the capillaries and begin ascending through the respiratory radicles until they reach the glottis; passing over the epiglottis, they enter the esophagus and are carried down to the small intestine, where they mature and become adult worms. The adult female *Ascaris* produces huge numbers of eggs—possibly 200,000 a day. To ensure adequate quantities of egg-requiring cholesterol, the parasite sequesters oxygen through a specially modified hemoglobin.[35] The entire cycle, beginning with the infective eggs and resulting in ovipositing females, lasts approximately 2 months. Infection is maintained in the community by the deposition of human stool in soil, which permits embryonated eggs to develop into the infective stage. This process takes approximately 2 weeks. The high prevalence of infection results not only from deficient sanitary facilities for disposal of human excreta but also from the deliberate use of human feces as fertilizer.

Epidemiology

In many regions of the developing world, *Ascaris* eggs are almost ubiquitous in the environment. All ages are affected by the parasite; young children, who are exposed more often to the contaminated soil, are affected most frequently. These children usually harbor greater numbers of adult worms in their intestine than do adults living under similar conditions.[24-26,32] High worm burdens in children also occur with *Trichuris* infections (see later discussion). Because the phenomenon of heavy *Ascaris*

and *Trichuris* worm burdens in childhood is found throughout most of the developing world, pediatric predisposition to "worminess" is widely thought to have a possible genetic or immunologic basis.[7]

Ascaris eggs are extremely hardy and resistant to extremes of temperature and desiccation, which may explain the common finding of high rates of ascariasis in impoverished urban environments (e.g., Guatemala City, Mexico City) and in rural environments. The eggs also are resistant to chemical disinfectants and are not destroyed readily by sewage treatment. In some areas, pigs may serve as a reservoir for zoonotic *Ascaris* infection.[27]

Pathophysiology

During the migratory phase of the infection, the larvae evoke an inflammatory response associated with eosinophilic infiltration. *Ascaris* antigens—so-called ABA-1 allergen—released during the molting of larvae evoke an immune response, and IgE antibodies directed against ABA-1 may be associated with resistance.[43] *Ascaris* larvae also release immunomodulatory glycosphingolipids that inhibit T-helper (Th) 1 responses.[3,32] Chronic ascariasis and trichuriasis may suppress host inflammation and even responses to vaccines by promoting a Th2-type cytokine profile.[46] There are also data to support a role for ascariasis in promoting susceptibility to malaria,[18] although not all studies confirm this finding. A controversial role of IgE anti-*Ascaris* antibodies is in protecting children against atopic states, including asthma.[42] During the intestinal stage of infection, symptoms derive primarily from the physical presence of the worms in the gut, from aberrant migration into other lumina, or from perforation into the peritoneum. As a protective mechanism for its own survival, *Ascaris* secretes peptides that block the action of pancreatic digestive enzymes (trypsin, chymotrypsin, elastase),[36,39] which may play a role in parasite-associated nutrient malabsorption, including the malabsorption of vitamin A.[31] Ascariasis also results in lactose intolerance.[31] Whether these phenomena provide the basis of observed *Ascaris*-associated physical growth retardation during childhood is unknown.[6,24-26,32,44]

Clinical Manifestations

The degree of disease induced by the migratory phase of *Ascaris* is related directly to the number of larvae migrating simultaneously. In light infections, this phase is typically unrecognized. Heavy infection, such as that induced in himself by Koino,[41] who swallowed 2000 infected eggs, may cause severe pneumonitis. In some regions of the world, pediatric *Ascaris* pneumonitis is seasonal.[3]

In the lumen of the intestine, *Ascaris* adult worms may become matted together and form a bolus large enough to cause intestinal obstruction, sometimes leading to bowel infarction and intestinal perforation. This is a particular problem in very young children because of the small luminal diameter of their intestines.[40] The incidence of this complication has been estimated at 2 per 1000 infected children per year.[28] Children with *Ascaris* obstruction exhibit a toxic appearance, often with signs and symptoms of peritonitis.[3] When recognized early, the obstruction can be treated with medical management, but in many cases surgical intervention is mandatory. Ascariasis has also been linked to chronic intussusception.[45]

Hepatobiliary and pancreatic ascariasis (HPA) results from blockage of the bile duct and pancreatic duct. Patients with HPA are subject to cholecystitis, acute cholangitis, "biliary colic," acute pancreatitis, or hepatic abscess.[40] In contrast to intestinal obstruction, HPA tends to be more common in adults, especially women.[40] Certain irritants, such as halogenated hydrocarbons (e.g., carbon tetrachloride and tetrachloroethylene, used in the past to treat certain hookworm infections), elevation of body temperature, and general anesthesia, have been known to precipitate aberrant migration. *Ascaris* screening by fecal examination should be considered before performing elective surgery on a child who might have immigrated recently from an impoverished area of the tropics.

Whatever the mechanism of interference by *Ascaris* with growth or nutrition, treatment with anthelmintics leads to substantial catch-up growth in previously parasitized children.[6,24-26,42,44] Ascariasis in pregnant women results in intrauterine growth retardation.[48] Most individuals with light infections rarely are symptomatic (they become aware of the parasites by passage of adult worms in stool or through regurgitating and vomiting the adult worms), although researchers have conjectured that even these individuals may exhibit subtle deficits in cognitive and intellectual development.[6]

Several cases of neonatal ascariasis have been described in the literature.[29,30] The mode of acquisition of these infections is unknown, but canine and feline ascarid infections commonly are acquired by a transplacental route, suggesting the possibility that this route also may occur in humans.

Diagnosis and Differential Diagnosis

The differential diagnosis of pneumonia caused by *Ascaris* suggests a parasitic etiology because of the peripheral eosinophilia. Any nematode with a migratory phase through the lungs can mimic this infection, however. *Ascaris* must be considered as a cause of intestinal obstruction in any geographic locale where its prevalence is high.

The diagnosis of intestinal ascariasis is established by identifying the characteristic ascarid eggs through microscopic examination of stool. Efforts have been made more recently to detect *Ascaris* metabolites in the urine by gas-liquid chromatography.[37,38] HPA is suspected in heavily infected children who have signs of biliary obstruction. Ultrasonography and endoscopic retrograde cholangiopancreatography are useful adjunctive diagnostic procedures for these conditions.[40]

Treatment

For an ordinary *Ascaris* infection, either albendazole administered at a fixed dose of 400 mg once or mebendazole administered at a fixed dose of 100 mg twice daily for 3 days is effective. A single fixed dose of 500 mg of mebendazole also may be effective, but it may be unsuitable for the treatment of other STH coinfections. As an alternative, pyrantel pamoate administered in a single dose of

11 mg/kg, not to exceed 1 g, is effective. In a systematic review it was shown that single-dose oral albendazole, mebendazole, and pyrantel pamoate result in ascariasis cure rates of 88, 95, and 88 percent respectively.[17] The benzimidazoles and pyrantel pamoate are not approved for children younger than 2 years old, and all the printed statements caution against the use of these drugs in the younger age group. An examination of the use of benzimidazoles in children 12 to 24 months old concluded, however, that these agents are probably safe and should be used if the circumstances warrant it.[44] In such cases, the dose of albendazole in these young children should be reduced to 200 mg.[3] The risk for treatment in this younger age group currently is undergoing more rigorous investigation because of mounting evidence that the growth and cognitive delay caused by STHs may be corrected with albendazole or mebendazole.[24-26,44,47] These drugs have a potential for embryotoxicity, however, so judicious use in young children is warranted. The World Health Organization is evaluating the use of benzimidazoles during pregnancy, particularly for use during the second and third trimesters.

In cases of intestinal obstruction, piperazine citrate may be effective because this drug paralyzes the myoneural junction of *Ascaris* and may result in relaxation of the matted bolus of worms. It is antagonistic to pyrantel pamoate, and these two drugs should not be administered together.

Management of intestinal obstruction or HPA often is surgical. For some patients, biliary decompression may be performed with endoscopic retrograde cholangiopancreatography.[40]

Prognosis

The prognosis is excellent in most cases of ascariasis. In patients with obstruction or perforation, the prognosis depends entirely on the speed of recognition and therapy.

Prevention

Ascaris infection could be eliminated entirely through proper disposal of human excreta. As an isolated means of health improvement in the world, this approach seldom is successful. Elimination of *Ascaris* from a community or a substantial reduction in the incidence of this infection usually occurs after general efforts in poverty reduction and improvements in the standard of living have been achieved. Periodic administration of community-wide therapy with anthelmintics has been effective in reducing worm burden as a short-term strategy. In the absence of aggressive sanitation and other control measures, however, re-infection can occur within 6 months after treatment in areas of high transmission,[2] although in areas of periodic therapy the intensity of infection is decreased, even if the prevalence is little affected.

TRICHURIS TRICHIURA

Trichuriasis has a prevalence approximating that of the other major intestinal nematode infections, or approximately 600 million cases worldwide,[1] but the infection usually is asymptomatic because in most cases it is light. Children with so-called asymptomatic light infection may have deficits in cognition, however.[6,19,64]

The infection is acquired by the ingestion of embryonated eggs acquired from the soil on hands or through contaminated food. The eggs hatch in the upper part of the small intestine, and the liberated larvae penetrate the villi. In contrast to the larvae of *Ascaris*, *Trichuris* larvae do not undergo extraintestinal migration but remain in situ for approximately 1 week, at which time they begin a progressive descent into the cecum and the colon. They mature there, and the attenuated anterior end of the adult worm embeds itself in the colonic mucosa. Creation of syncytial tunnels (derived from the columnar epithelium of the colon) is facilitated by the release of a parasite-derived, pore-forming protein.[54] The parasites derive their nourishment from these colonic mucosal tunnels. The entire cycle from the ingestion of embryonated ova to the development of sexually mature adults takes approximately 2 months. Persistence of the infection in a community depends on continual contamination of the soil with human feces.

Epidemiology

These parasites are found most commonly throughout the developing countries of the tropics and subtropics. The distribution of this worm often parallels that of *Ascaris*. In addition, as in the case of *Ascaris*, children with trichuriasis usually harbor greater numbers of worms than adults living under similar conditions.[51,52] Consequently, children have greater morbidity from trichuriasis than adults do. The mechanistic basis of added worminess in children is unknown, although researchers have observed that for all of the soil-transmitted helminthiases, including trichuriasis, infections are aggregated, with a few children having particularly heavy infections. These heavily infected children seem to have a genetic or immunologic predisposition to *Trichuris* infection.[51,52] Children also are the major source of *Trichuris* eggs in the environment, which when deposited in the soil become infective in approximately 1 month and remain viable for several months. They are killed by exposure to temperatures greater than 40° C within 1 hour. Freezing temperatures less than –8° C also destroy these eggs. Similar to ascarid eggs, they are resistant to chemical disinfectants.

Pathophysiology

At the site of attachment, the adult worm elicits characteristic changes in the colonic mucosa as noted earlier. Inflammatory cells also are found at these sites, but they do not seem to account entirely for the clinical resemblance of trichuriasis to some forms of inflammatory bowel disease.[51,60] Similar to many other intestinal worms, *Trichuris* is expelled through the action of the host's immune system. This expulsion results from a combined effect of antibody and lymphoid cells.[65] Regulation of *Trichuris* populations in the gut has been ascribed to a carefully orchestrated balance of host-derived cytokines.[55] Although anemia has been attributed to trichuriasis,[58] the

amount of blood loss caused by this parasite is much less than hookworm-associated blood loss and is insufficient to account for anemia.[59] One possibility is that *Trichuris*-induced anemia results from chronic inflammation, similar to the anemia of inflammatory bowel disease.[51,52]

Clinical Manifestations

Two major disease syndromes are caused by heavy *Trichuris* infection during childhood.[51,52] *Trichuris* dysentery syndrome (TDS) is associated with severe diarrhea with blood and mucus. It can also be associated with chronic iron-deficiency anemia,[56] although anemia should be considered first and foremost a hallmark of human hookworm infection. Children with TDS are anemic and frequently manifest growth retardation and failure to thrive.[53] Infants and toddlers with TDS are at risk for protracted tenesmus, which leads to rectal prolapse. *Trichuris* colitis is a more chronic manifestation of moderate to heavy infection that is characterized by a form of inflammatory bowel disease similar to what occurs in Crohn disease or ulcerative colitis. Children with this form of colitis also can have chronic malnutrition and short stature. Moderately and heavily infected (and possibly even lightly infected) children are at risk for having deficits in cognition and intellectual development.[64]

Diagnosis and Differential Diagnosis

The diagnosis is established by identification of the characteristic barrel-shaped eggs through microscopic examination of stool. Clinically, heavily infected children with TDS may resemble children with amebic or bacillary dysentery. Children with *Trichuris* colitis may have signs and symptoms that resemble other forms of inflammatory bowel disease. The erythrocyte sedimentation rate is not elevated in children with *Trichuris* colitis, however. Among other diagnostic modalities, *Trichuris* colitis has been detected by Doppler ultrasonography,[50] whereas the presence of adult worms can also be seen on colonoscopy.[63]

Treatment

In the past, when noxious or toxic drugs had to be used, only patients with heavy infection were treated. Currently, any patient with this infection can be treated by the administration of either albendazole, administered as a single fixed dose of 400 mg in MDA programs or on 3 successive days otherwise, or mebendazole 100 mg twice daily for 3 days.[61] A single dose of 500 mg of mebendazole also is used for MDA in some developing countries. A recent systematic review, however, has revealed that cure rates after single-dose oral albendazole and mebendazole are only 28 and 36 percent, respectively.[17] Recent studies indicate that the efficacy can be approved by using a double dose of albendazole or mebendazole given 8 hours apart.[62] A combination of albendazole and mebendazole was also effective,[62] as was adding ivermectin to either albendazole or mebendazole.[57] As noted earlier, the safety of the benzimidazoles in very young children has not been established, but this may not preclude its use in the practice of pediatrics.[39] As an alternative, the drug oxantel is effective for the treatment of trichuriasis. In some countries, oxantel is formulated with pyrantel pamoate.[51]

Prevention

As in the case of other nematodes, sanitary disposal of excreta—but more important, improvement in the standard of living—tends to reduce the incidence of infection. Frequent mass treatments with mebendazole reduce the worm burden in a community.

HOOKWORMS

Hookworm infection is one of the most important infections of adults and children in the developing world, with an estimated prevalence of approximately 600 million cases.[3,10] Hookworms exert their pathogenic effect by causing intestinal blood loss, which leads to iron-deficiency anemia.[76] By considering the average daily blood loss induced by each worm, a moderate hookworm infection comprising 25 adult hookworms produces 1 mL of blood loss per day, often sufficient blood loss to rob a child of his or her daily iron requirement.[73] Because loss of blood represents loss of erythrocytes *and* plasma, heavy infections also contribute to protein malnutrition.[78]

Two major species of hookworms infect the human intestine: *Ancylostoma duodenale* and *Necator americanus*, although *N. americanus* is found more commonly worldwide (responsible for more than 80 percent of the global hookworm burden), especially in sub-Saharan Africa, Southeast Asia, and the Americas.[76] Two other members of the genus *Ancylostoma*, *A. ceylanicum* and the dog hookworm *A. caninum*,[80] are much less frequent causes of intestinal pathology in humans.[76]

The infection is acquired either by exposure of skin to moist soil infested with the larvae of these worms (*A. duodenale* and *N. americanus*) or by ingestion of the infective larvae (*A. duodenale* only). The most propitious circumstances for infection are shady areas and sandy or loamy soil. Infection is particularly likely to occur early in the morning, when the ground is moist with dew, or after a rainfall. After the larvae enter the host, they initiate a developmental program that continues until they enter the intestine.[7,76] This process is coupled to the release of parasite-derived proteases and other virulence factors.[86] Larvae that enter through the skin are carried by the venous circulation to the right ventricle and there follow the route described for *Ascaris*, whereas larvae that are ingested may develop entirely within the gastrointestinal tract.

On reaching the small intestine, the larvae mature to adult worms, which become attached with their mouth parts to the intestinal mucosa. The worms sustain themselves by releasing hydrolytic enzymes that degrade the intestinal mucosa and then feed on cellular and connective tissue debris.[76] During this process, capillaries and arterioles are eroded and lacerated, with subsequent extravasation of blood. The adult worms also ingest hemoglobin in blood through the action of parasite gut

brush border proteases.[84] Anticoagulants that block the activity of host factor Xa and VIIa/tissue factor facilitate blood flow and are responsible for continued bleeding from the original site after the worm has moved to a new one.[72]

The entire cycle from penetration of the skin or ingestion of larvae to the development of mature worms usually takes 6 to 8 weeks. At that time, hookworm eggs appear in the feces. *A. duodenale* larvae also may undergo a period of developmental arrest within the human host that lasts weeks or months. Intestinal ancylostomiasis can occur up to 1 year (and possibly longer) after initial exposure to infective larvae has occurred.[81,82] Investigators have conjectured that the reservoir of arrested *A. duodenale* larvae enters the mammary glands and breast milk.[75] This sequence of events may account for cases of infantile ancylostomiasis noted in Africa, India, and China.[67,71,75] Humans are the major reservoir of these organisms, and this infection is maintained by continual contamination of soil by human feces.

Epidemiology

Although in ancient times these parasites had a worldwide distribution, they currently are most prevalent in areas of rural poverty in the tropics and subtropics. *A. duodenale* predominates in many parts of the Indian subcontinent and focal areas of China north of the Yangtze River.[7] *N. americanus* is the predominant hookworm in the world, especially in the Western Hemisphere, most of Africa, China south of the Yangtze River, Southeast Asia and Indonesia, and certain islands of the Pacific. *A. duodenale* also is a major parasite in Egypt and other parts of the Mediterranean region, Africa, and a few focal areas in South America, including Paraguay and northern Argentina. A small Central American focus also exists in southern Honduras and El Salvador, and one exists among aboriginal populations in Australia. This differential distribution is not always absolute, and small numbers of either parasite can be present where the other predominates. Mixed infections with both species are common. *A. ceylanicum* occurs in focally endemic areas of southern Asia,[76] whereas the dog hookworm *A. caninum* has been described as a cause of human eosinophilic enteritis in Australia and possibly elsewhere.[78]

Larvae survive in soil for 6 weeks. They are destroyed by drying, freezing temperatures, and heat greater than 45°C. Hookworm infection occurs in areas with high agricultural intensity and is not found frequently in urban areas, where *Ascaris* and *Trichuris* might predominate. Because shade and moisture are essential for survival at the infective larval stage, a not surprising finding is high rates of hookworm infection in families that harvest tea in India and Bangladesh, mulberry leaves (for the silkworm industry) in eastern China, sweet potatoes and corn in western China, coffee and bananas in Central and South America, and rubber in Africa.

Similar to other STHs, hookworm infections usually are aggregated such that most individuals harbor light worm burdens, whereas a substantial minority harbor moderate or heavy infections.[76,82] Even after receiving specific anthelmintic chemotherapy, moderately and heavily infected individuals seem to be predisposed to the reacquisition of heavy infection.[82] A predisposition to hookworm infection may have a genetic or immunologic basis.

In contrast to the other STHs, high rates of hookworm infection occur in adults and children. In some regions, the age-associated prevalence and intensity increase linearly, with the heaviest infections occurring in elderly populations.[74] Hookworm coinfections with strongyloidiasis,[66] schistosomiasis,[10,85] and malaria[68,69] have been described and are believed to be common in low- and middle-income countries.

Pathophysiology

During the migratory phase of the infection, the larvae evoke an inflammatory response associated with eosinophilic infiltration. Immune responses to the infection have been difficult to study in humans, but in an animal model a dog infected with *A. caninum* can be rendered immune to challenge infection by receiving repeated dosing with the infective larvae. This observation has provided a means of producing a live attenuated larval vaccine in the laboratory, but it is unsuitable for humans.

Hookworms feed on human blood and have the capacity to lyse red blood cells and degrade host hemoglobin.[79] The major source of injury to the host is loss of blood, with *A. duodenale* producing greater blood loss than *N. americanus*. Rarely, massive bleeding has been reported.[80] Iron-deficiency anemia results when iron loss exceeds the host's iron reserves. Because children and women of reproductive age generally have lower iron reserves than do other populations, they are at the highest risk for developing hookworm disease and anemia.[76] Recent systematic reviews confirm the association between anemia and hookworm infections in children and pregnant and nonpregnant adults.[70,83] Long-standing moderate and heavy infections result in the characteristic features of severe iron deficiency. Loss of protein contributes further to malnutrition. Together the iron and protein malnutrition result in impaired growth and physical fitness.[21,24-26,76] In some cases, hypoproteinemia can be corrected by a high-protein diet without deworming the patient,[80] although the World Food Program and other international agencies now frequently incorporate deworming into their nutritional supplementation programs. In addition to the physical deficits noted earlier, hookworms may affect cognitive development because iron is important for the development of dopaminergic neurons and for the biosynthesis of some neurotransmitters.[76] An experimental human hookworm vaccine for *N. americanus* infections is under development; the vaccine targets key parasite enzymes involved in blood digestion and heme detoxification.[10]

Clinical Manifestations

Penetration by larvae causes "ground itch" or "dew itch," a pruritus that occurs after walking in the morning dew. These cutaneous manifestations can occur on almost any part of the body. This phase of early infection is followed within days to weeks by a pneumonitis, which typically is less pronounced than *Ascaris* pneumonitis.

The acute intestinal phase in heavy infections is characterized by abdominal pain, diarrhea, nausea, and anorexia.[75] Eosinophilia occurs approximately at the onset of the intestinal phase. Subsequently, well-nourished individuals with light infections have mild gastrointestinal symptoms, but no evidence of anemia or malnutrition. At the other extreme, children with moderate hookworm infections can show signs and symptoms of iron-deficiency anemia, whereas heavily infected children can have hemoglobin values of 2 g/dL and edema or anasarca caused by hypoproteinemia. Infants with severe ancylostomiasis can exhibit failure to thrive, profound pallor, and melena.[67,71,75]

Deficits in physical and intellectual growth as a result of chronic hookworm infection in childhood have been reported since the early part of the 20th century.[6,7,21,22,76] Some recovery has been described after "deworming," although some deficits occurring in infancy may be irreversible.

Diagnosis and Differential Diagnosis

Hookworm pneumonitis resulting from the early migratory stages typically is nonspecific in its presentation and difficult to diagnose. Hookworm anemia is caused by blood loss; it must be distinguished from all other causes of intestinal loss of blood. In developing countries, where severe hookworm anemia is common, the probability of the occurrence of rarer causes of intestinal blood loss, such as Meckel diverticulum and polyps, is low. The opposite holds true for regions where hookworm infections are light or infrequent. In sub-Saharan Africa, the distribution of hookworm overlaps with other significant causes of so-called agricultural anemias, including malaria, schistosomiasis, malnutrition, and hemoglobin polymorphisms.[14]

The diagnosis is established by identifying the characteristic eggs by microscopic examination of stool. The eggs of *A. duodenale* and *N. americanus* cannot be distinguished from each other by morphologic criteria, but the worms can be differentiated by direct examination of the infective larvae or adults. One must assume that it is one or the other species on the basis of the geographic origin of the patient. Although this decision is not of paramount importance, it does have some therapeutic implications, including the possibility that arrested larvae of *A. duodenale* would become reactivated and either repopulate the intestine at some point after treatment or enter breast milk during or after parturition. Hookworms have been detected visually by endoscopy.[77]

Treatment

For *N. americanus* infection, the drug of choice is either albendazole, administered at a fixed dose of 400 mg, or mebendazole, given as 100 mg twice daily for 3 days. In settings of MDA for low-income countries, mebendazole is sometimes given as a single 500-mg dose. Pyrantel pamoate given as a dose of 11 mg/kg, not to exceed 1 g, for 3 days is a suitable alternative drug. A recent meta-analysis and systematic review found that the efficacy of single-dose oral albendazole for hookworm infection was 72 percent, whereas single-dose mebendazole only results in a cure rate of 15 percent and pyrantel pamoate in one of 31 percent.[17] Therefore, albendazole should be considered the first-line treatment of hookworm infection. In areas endemic for ancylostomiasis, the health care provider should be aware of the potential of arrested tissue larvae to repopulate the intestine or enter breast milk and infect infants during the perinatal period. Iron supplementation and transfusion are occasional important adjunctive therapies for severe hookworm disease.

Prevention

As in all cases of all STH infections, the sanitary control of the disposal of excreta represents an important public health control measure. Accomplishing effective sanitation in resource-poor settings has not been feasible in most of the developing world. The popular recommendation to wear shoes is naïve because *N. americanus* larvae also enter through the upper extremities, torso, and legs, and because *A. duodenale* also is orally infective. Studies to develop and test a first-generation recombinant hookworm vaccine are in progress.[10]

ENTEROBIUS VERMICULARIS

Pinworm infection (enterobiasis), or oxyuriasis (the older term), is one of the most frequent of all human helminth infections and one that is common in North America and Europe.[97] Some investigators believe that the overall prevalence of enterobiasis is declining in the United States, however. Most infected individuals are children, and the infection is found in all socioeconomic classes. It is acquired by the ingestion of infective eggs picked up on the perianal skin, in the air, or on bedclothes and underwear. Swallowed eggs, transmitted to the mouth by fingers or through inhalation, hatch in the duodenum, and the liberated larvae undergo additional maturational steps in the small intestine before reaching the cecum. There, the sexually mature worms copulate and proceed to the rectum and eventually to the perianal skin, where the gravid females lay eggs. The eggs become infective within 2 to 4 hours after deposition.

The entire cycle from ingestion of the egg to the egg-laying phase of the gravid female is 4 to 6 weeks. Rarely, a retrograde infection occurs in which eggs hatch on the anal mucosa and the larvae migrate up the bowel and mature to adult worms. Sexual transmission from oral-anal contact has also been reported.[87] Although enterobiasis is a human infection, anthropoid apes can be infected experimentally.

Epidemiology

The infection is worldwide in distribution, and children are infected most frequently. Communal living, especially assembling in school gymnasia and living in crowded households, promotes transmission of the infection. Adults tend to be infected through their contact with children; parents and teachers are the most vulnerable. Orphanages and daycare centers frequently are affected.[97]

Pathophysiology

No intestinal reactions occur during the migratory phase, and because no tissue migration takes place, no eosinophilia occurs to the degree seen with some other nematodes. Occasionally, hypersensitive individuals may have a slight increase in eosinophils. The deposited ova induce pruritus on the perianal skin. No evidence indicates that some individuals are more susceptible than others to this infection.

Enterobius occasionally has been found in vermiform appendixes removed at surgery.[88] A causal relationship to appendicitis has not been established, but some evidence points to the possibility that this worm induces granuloma formation and may cause obstruction of this vestigial structure.[89]

When the adult gravid female migrates along the perineal skin into the vagina, it may cause vulvitis as a reaction to the eggs deposited in that region.[91] Some investigators speculate that migrating pinworms may introduce bacteria into the lower urinary tract and result in urinary tract infection.[96] *E. vermicularis* has also been reported from the fallopian tube and as a cause of infertility.[99] Other aberrant infections, such as those causing hepatic granuloma and renal disease, occur more infrequently.[90,94]

Clinical Manifestations

Pruritus is the most common symptom; its intensity varies from mild perianal itching to acute, intractable pain. Secondary cellulitis also may occur in severely pruritic cases.[93] Perianal abscess has also been described.[95] Vaginal discharge and vulval itching are symptoms in the rare cases in which a worm has migrated into the vagina. Insomnia, restlessness, irritability, loss of appetite, loss of weight, and grinding of teeth all have been reported anecdotally in individuals with pinworm infection, but no evidence has shown that any of these symptoms is related causally to *Enterobius* infection. Enuresis also has been blamed on the pinworm, but one epidemiologic study failed to determine the causality.[98] An unusual form of eosinophilic ileocolitis resulting from massive infestation with many *E. vermicularis* larvae has been described in a homosexual man.[92] A variety of clinical manifestations resulting from ectopic infections, including appendicitis and infertility have been reported.[88,99]

Diagnosis

E. vermicularis eggs are identified readily by low-power microscopic examination of transparent adhesive tape previously applied to the perianal skin and then affixed to a microscope slide.

Treatment

Single-dose therapy with mebendazole (100 mg), albendazole (400 mg), or pyrantel pamoate (11 mg/kg, not to exceed 1 g) is effective. With the current availability of these three highly effective drugs, the intensive laundering of underwear and bed clothing, recommended in the older literature, no longer is necessary. Treating all members of the household is advisable, however, because they all must be presumed to be infected. Re-treatment in 2 or 3 weeks to destroy any adult worms that have hatched from the eggs swallowed at the time of initial therapy may be necessary. None of these drugs destroys the eggs.

One of the most important aspects of management of this infection is reassurance that in some areas its ubiquity virtually precludes effective eradication. Re-infection can be anticipated in any family infected with pinworms because of the high prevalence of this worm in the community. It also is important to reassure families that the presence of pinworms does not suggest poor hygienic standards in the family.

STRONGYLOIDES STERCORALIS AND *S. FUELLEBORNI KELLYI*

Strongyloides stercoralis and *S. fuelleborni kellyi* are among the most virulent helminthic pathogens of humans, although human strongyloidiasis is believed to be less prevalent than *Ascaris* or hookworm, with some estimates indicating 30 to 100 million cases worldwide.[123] *S. stercoralis* has the unusual ability to cause autoinfection, which can lead to hyperinfection and disseminated infection in immunocompromised hosts.* *S. fuelleborni kellyi* causes an aggressive infantile protein-losing enteropathy that leads to ascites and high mortality rates.[100,101]

S. stercoralis infection is acquired by the exposure of skin to infective larvae in the soil, much as in the case of hookworm infection. Similar circumstances that promote the survival of hookworm larvae in soil (i.e., moisture, sandy or loamy soil, and shade) promote the survival of *Strongyloides*. Larvae penetrate skin, facilitated by a potent histolytic protease that they secrete.[103,122] From the moment of penetration of the skin to the arrival of the worms in the intestine, the cycle commonly is thought to be similar to that of hookworms, although experimental evidence suggests that *S. stercoralis* also may explore routes of migration that bypass the lungs.[128] Within the intestine, the small adult worms do not attach to the mucosa as hookworms do but instead lie embedded in its folds. The cycle from penetration of skin to development of mature worms in the intestine is approximately 28 days.

No parasitic adult male worms exist to fertilize the eggs. Instead, the mature eggs may develop by parthenogenesis. In addition, in contrast to the eggs of other parasitic nematodes, these eggs usually are not found in feces but instead embryonate within the intestine and develop into larvae, which are deposited in soil with human stool. These so-called rhabditiform larvae must molt before they become infective.

This cycle has two variations. One permits the development of nonparasitic male and female adults in soil, which can maintain infestation of the soil for a certain period; this free-living phase sometimes is called the *heterogonic life cycle*. The second variation has much greater

*References 106, 110, 113-117, 119, 125, 126.

clinical relevance. Under certain conditions that are not well defined, the rhabditiform larvae molt to new infective larvae while still in the intestine. These new infective larvae can penetrate the intestine and set up a new cycle, commonly called *autoinfection* or the *autoinfective cycle*.[115] In this fashion, this nematode, in contrast to most other intestinal nematodes of humans, actually can increase in number without reinfection from the outside world. This phenomenon also is responsible for persistence of this infection for decades in an untreated host.[117] Some investigators think that low levels of autoinfection occur in most patients with strongyloidiasis.

When host defenses are impaired, especially through use of high-dose corticosteroids (discussed later), *S. stercoralis* can undergo multiple rounds of autoinfection, leading to the production of thousands to hundreds of thousands of adult parasites in the intestine. This phenomenon is known as *hyperinfection*.[104,110,116,125] One possible consequence of hyperinfection is disseminated infection, in which larval and adult worms are identified at extraintestinal sites.

S. fuelleborni kellyi larvae are passed to infants by ingestion in breast milk.[100,105] Transmammary infection by nematode larvae is an extremely common route of transmission in nonhuman nematode infections[20]; although not well studied, it probably also occurs commonly in humans.

Epidemiology

S. stercoralis infection has worldwide distribution, but it is most prevalent in tropical and subtropical regions.[123] In North America, strongyloidiasis is focally endemic in some parts of Appalachia[106] and is common in Southeast Asian immigrants.[118] In one study, 76.6 percent of Kampuchean immigrants and 55.6 percent of Laotian immigrants were seropositive for *S. stercoralis* infection.[118] Between 1991 and 2006 an estimated 347 deaths from strongyloidiasis occurred in the United States, mostly among older white males and those living in the southeastern states.[109] Strongyloidiasis also is endemic in Brazil and Jamaica and presumably elsewhere in Latin America, as well as in sub-Saharan Africa.[111,123,126] Because of the possibility of autoinfection and, by extension, infection through contamination of skin by infested feces, strongyloidiasis is highly prevalent in mental hospitals, prisons, and homes for mentally disabled children. Dogs and anthropoid apes may serve as animal reservoir hosts for *S. stercoralis*. *S. fuelleborni kellyi* infection is endemic in Papua New Guinea and parts of sub-Saharan Africa.[100,101,120]

Pathophysiology

During the migratory phase of the infection, the larvae of *S. stercoralis* evoke an inflammatory response associated with eosinophilic infiltration. The adult phase in the intestine, even in moderate infection, may be associated with an inflammatory reaction sufficient to be symptomatic. Some evidence suggests that *Strongyloides* induces a malabsorption syndrome, which has been treated effectively by deworming.[106,124] It also has been noted, however, that the diarrhea associated with strongyloidiasis in young children occurs more frequently in those with underlying malnutrition.[110] Young children with *S. stercoralis*–induced malabsorption experience stunted growth and failure to thrive.[106]

The deficits in host defense that promote hyperinfection and disseminated strongyloidiasis are not well understood. Although cell-mediated immune deficits, such as those occurring in immunosuppression, organ transplantation, severe malnutrition, and cytotoxic chemotherapy for neoplasms and collagen vascular disease, are associated with this phenomenon, certain established deficits in cell-mediated immunity, such as those in HIV infection, do not trigger hyperinfection.[115] Researchers have suggested that patients receiving large doses of corticosteroids are particularly susceptible to hyperinfection because the corticosteroids themselves function as direct signals or ligands for the parasite to undergo autoinfection.[115] Patients with human T-cell lymphotropic virus type I seem to be at high risk for acquiring opportunistic strongyloidiasis,[113,119] possibly because of a specific deficit in their effector IgE immune response.[126] The pathogenesis of the marked protein-losing enteropathy that leads to ascites in the swollen belly syndrome of *S. fuelleborni kellyi* infection has not been established.

Clinical Manifestations

During the migratory phase of larval strongyloidiasis, patients may be susceptible to the development of pneumonitis associated with eosinophilia. Larval migration through the skin can result in larva currens. Although most patients harboring *S. stercoralis* in their intestine are asymptomatic, patients with moderate or heavy infection classically have intense diarrhea productive of watery, mucous stool. Periods of alternating diarrhea and constipation may occur. Anorexia and cachexia, which lead to failure to thrive and other deficits in physical growth, are common features of pediatric strongyloidiasis.[106] Eosinophilia is also common, although among pediatric refugees this sign was not considered predictive for *S. stercoralis* infection.[112] Chronic strongyloidiasis has been linked to nephrotic syndrome.[108]

In disseminated strongyloidiasis caused by the hyperinfective cycle, larvae may invade all tissues, including the central nervous system (CNS). Because larvae penetrate the intestine, they may carry with them enteric flora and cause sepsis or meningoencephalitis.[104] Although diarrhea is the most commonly recognized consequence of *Strongyloides* infection, the hyperinfective cycle has the greatest portent for immunosuppressed patients. Infants with *S. fuelleborni kellyi* infection may manifest the swollen belly syndrome with marked abdominal ascites and pleural effusions that can be fatal. In older children *S. fuelleborni* kellyi infection can be associated with malnutrition.[120]

Diagnosis and Differential Diagnosis

Strongyloides pneumonitis can resemble the clinical manifestations associated with the lung migration of other nematode parasites, such as *Ascaris* and hookworm. The differential diagnosis of diarrhea must include causes of

chronic diarrheal disease. In some patients, eosinophilia is a presenting sign of strongyloidiasis, either in patients with diarrhea or even in asymptomatic immigrants from developing countries.

The diagnosis is established by identification of the characteristic larvae during microscopic examination of stool, which is not easy because rhabditiform larvae usually are not produced in abundance. Specific stool concentration techniques are available to increase the sensitivity of fecal examination, although they are not as effective as amplifying the heterogonic life cycle by the Baermann technique or by looking for characteristic larval tracks on nutrient agar plates.[129] The stool of all immunosuppressed individuals, including those given corticosteroids for any reason, who have ever been in a region where *Strongyloides* is found must be examined to rule out this infection. If routine stool examination results are negative, the stool should be processed as outlined earlier. In addition, examination of duodenal contents can be attempted by the string test (Enterotest). This examination only divulges the contents of the duodenum, however, and can miss the larvae in the lower part of the small intestine. An enzyme-linked immunosorbent assay (ELISA) for detection of *Strongyloides*-specific antibodies is available on a research basis.[118,126]

Children with the swollen belly syndrome from *S. fuelleborni kellyi* infection shed eggs rather than larvae in their feces. Large numbers of eggs are common findings in clinical cases.

Treatment

Previously, the drug of choice for *S. stercoralis* and *S. fuelleborni kellyi* infection was thiabendazole.[107] The drug has high toxicity, however, which frequently includes nausea, vomiting, and vertigo and sometimes requires interruption of therapy. Rarely, it induces leukopenia, rash, and Stevens-Johnson syndrome. Because the drug is detoxified in the liver, its dose may have to be reduced for patients with liver failure. Another benzimidazole used with increasing frequency is albendazole 400 mg twice daily for 7 days. Recent studies have shown that ivermectin is equivalent to thiabendazole in terms of its efficacy, but ivermectin has a much better safety profile.[102] Similarly, single and double doses of oral ivermectin are more effective than a 7-day course of high-dose albendazole for patients with *S. stercoralis* chronic infection.[130]

Ivermectin is considered the treatment of choice for strongyloidiasis. It is administered at a dose of 200 μg/kg/day for 2 days. Treatment with ivermectin gives a cure rate of 80 percent.[119,121] The safety of the drug in young children (<15 kg) and pregnant women remains to be established. Because the mortality rate of patients with disseminated strongyloidiasis remains high despite specific anthelmintic therapy, a common practice is to treat with a prolonged course or with a repeat course. In addition, several case reports have now described the use of veterinary parenteral formulations in patients too ill to take oral medications[121] or the use of ivermectin combined with albendazole.[124] Secondary bacterial complications, such as sepsis and meningitis, are common with disseminated strongyloidiasis, so judicious use of broad-spectrum antimicrobial agents frequently is indicated for this condition. As an additional supportive measure, patients who have hyperinfective strongyloidiasis and are receiving high-dose corticosteroid therapy probably benefit from steroid taper. Patients with transplants and cyclosporine immunosuppression may benefit from some of the direct helminthotoxic properties of this compound.[127]

Prognosis

The prognosis is excellent in patients who do not have disseminated infection and are treated promptly. Unrecognized disseminated infection can be lethal.

Prevention

Proper disposal of human excreta substantially reduces the prevalence of strongyloidiasis in any community. In closed institutions, where control of direct spread is not likely to be achieved, identification plus treatment of infected individuals is the only feasible control.[114]

ABERRANT INFECTIONS WITH INTESTINAL NEMATODES

TOXOCARA CANIS AND *T. CATI*

As indicated in the previous sections, the life cycles of the intestinal nematodes are adjusted precisely through evolutionary selection. In many instances, only one host in which the cycle can be completed is parasitized by the nematode. Infection of an unnatural host, in most cases, leads to complete failure of development and causes no disease. In a few instances, an infection may be established, but the cycle is not completed. Under such circumstances, the process of aberrant migration of larvae may be more pathogenic than steps in the natural cycle.

One of the most dramatic examples of an aberrant infection is visceral larva migrans, caused by infection with *Toxocara canis.* This roundworm causes intestinal infection in the dog, in which its cycle resembles that of *A. lumbricoides* in humans. Humans become infected by *Toxocara* through the ingestion of an embryonated egg, much as in human infection with *Ascaris.* Larvae hatch in the small intestine, penetrate the villi, and begin a migration that takes them through every organ and tissue of the body. Because they cannot mature, the larvae tend to migrate for months until they are overcome by the inflammatory reaction of the host and die. Although

larvae of other toxocarids such as *T. cati* and *Toxascaris leonina* have been suggested as possible causes of visceral larva migrans, they may be less important as zoonotic pathogens in humans.

Because population-based serologic testing is limited to only a handful of research studies,[131,143,151,152] the prevalence of toxocariasis in North America and elsewhere may be underestimated. According to some investigators, *T. canis* infection may have replaced *E. vermicularis* as the most common helminth parasite in the United States.[16]

Epidemiology

The prevalence of toxocariasis is difficult to assess because of the failure of establishing the diagnosis in many cases. The disease has been reported from many parts of the world, including temperate climates, and one can assume that it is found wherever humans and dogs coexist. High prevalence rates of the infection have been reported from Brazil, Africa, Eastern Europe, and the United States[8,12,16,137]; toxocariasis may represent one of the most common helminth infections worldwide.[16] Young children often come into contact with *T. canis* eggs while playing in sandboxes and on playgrounds that were contaminated by a family pet.[145,147] The level of contamination of public areas also is difficult to ascertain. In several studies, ova were present in 5 to 25 percent of soil samples obtained, and surveys of dogs in urban communities have shown the occurrence of frequent infections, particularly in puppies, which are infected almost universally with *T. canis* (canine infection occurs transplacentally).[140,141]

Subsequent dissemination of *T. canis* eggs in the environment probably is aided by migrating earthworms and other soil invertebrates.[136] The seroprevalence of toxocariasis in the United States is high, and the parasite should be considered an emerging pathogen in some poor rural and urban areas. In some groups of socioeconomically disadvantaged black children, the seroprevalence is 30 percent,[144,150] with even higher rates occurring among U.S. inner-city Hispanic children.[152] In the United States, the disease is linked to being poor and of African-American or Hispanic ethnicity.[8,16,138,155] It has been estimated that up to 2.8 million African Americans have toxocariasis, so this disease represents a major but neglected health disparity.[8] Toxocariasis is endemic to Puerto Rico. Major risk factors for acquiring toxocariasis include having a litter of puppies in the home and the habit of geophagia.[148] The latter risk factor probably accounts for the observed association between toxocariasis and elevated lead levels.[148] In Ireland, the prevalence of ophthalmologist-diagnosed ocular toxocariasis is 9.7 per 100,000, while in the United States it was determined that 68 patients were newly diagnosed with ocular toxocariasis between September 2009 and September 2010.[135,145]

The presence of a positive skin test for toxocariasis is associated with poliomyelitis statistically.[156] No direct causal relationship exists; possibly, the circumstances leading to ingestion of *Toxocara* ova also are conducive to ingestion of poliomyelitis virus. *Toxocara* and *Toxoplasma* coinfections have also been noted; possibly these are from *T. cati* infection reflecting concurrent exposure from cats.[146] Likewise, seizures and asthma are correlated with seropositivity for *Toxocara* antibodies, but a causal relationship has not been established.[16,131] Some investigators have postulated that toxocariasis may be an important cause of asthma and so-called idiopathic seizures in young children.[16,142,145]

Pathophysiology

The entire infection is restricted to the migratory phase and bears some clinical resemblance to the symptoms found during the early phases of *A. lumbricoides* infection. Symptoms are protean and depend on which organ or tissue is infected. For unknown reasons, visceral migration through the liver, lungs, and brain occurs more commonly in toddlers and children younger than 5 years old, whereas older children are more likely to exhibit only ocular involvement.[145,147] Epidemiologic evidence suggests that this infection produces two distinct syndromes, visceral and ocular, because involvement of one tends to occur in the absence of the other.[143] Visceral migration elicits eosinophilic granuloma formation in the target organs and leads to hepatitis, pneumonitis, or cerebritis. Larval migration in the retina results in ocular larva migrans, which includes granuloma formation in the retina.[132,139,153] The lesion can resemble retinoblastoma so that it often is confused with it. Endophthalmitis[139] or papillitis[136] also may develop. Invasion of other organs and tissues induces granuloma formation.

Clinical Manifestations

Most patients infected with *T. canis* are thought to be asymptomatic. Some of these individuals have isolated findings, including eosinophilia, or wheezing and asthma. The term *covert toxocariasis* is used by some investigators to describe these patients, who often are identified by their circulating anti–*T. canis* antibody titers. An association between asthma and covert toxocariasis has been well described in Europe, but as yet this association is unproven in North America.[152] Potentially, this association would represent an important avenue for investigation, given the high prevalence rates among African-American and Hispanic children who live in poverty in the United States and are considered at high risk for asthma.[16]

Visceral larva migrans, the extreme form of toxocariasis, typically occurs in a toddler with the symptoms and signs of a multisystemic disease. It is associated with fever, hepatosplenomegaly, lung infiltrates accompanied by wheezing, a high degree of eosinophilia (approaching 80%), and elevated immunoglobulin levels, particularly of the IgM class.[142,145,147,148] Seizures and neuropsychiatric disturbances also are common. In one case report, the child's major neurologic manifestation was a static encephalopathy.[142]

In contrast, ocular larva migrans is characterized by a unilateral vision deficit and, sometimes, strabismus. Ophthalmologic examination frequently reveals one or more posterior poles or peripheral pole granulomas.[139,147,153] More global eye inflammation also can occur (discussed

earlier). Children with ocular involvement usually have few, if any, systemic manifestations. Often, no laboratory abnormalities are detected.

Diagnosis and Differential Diagnosis

Visceral larva migrans must be distinguished from the migratory phase of the other nematode infections. Because of hepatosplenomegaly and hypereosinophilia, eosinophilic leukemia occasionally has been suspected, but it can be ruled out readily by examining bone marrow.

T. canis larvae can be identified in tissues in liver biopsy specimens, but the diagnostic yield is low. One must resort to indirect means and be aware that a multisystemic disease with elevated IgM and hypereosinophilia fits the diagnostic criteria. An ELISA available at the Centers for Disease Control and Prevention is highly specific and diagnostic.[147,150,151] However, the exact interpretation of being seropositive to *T. canis* is considered controversial, with some investigators of the opinion that this finding reflects previous exposure whereas others believe it indicates the presence of actively migrating larvae.

Ocular larva migrans usually is diagnosed by an experienced ophthalmologist who recognizes the characteristic granulomas and larval tracks on retinal examination. Presumably because of minimal antigen presentation by a few migrating larvae in the eye, often no measurable immune response occurs in this condition. For this reason, ELISA frequently is unreliable for establishing the diagnosis of ocular larva migrans.[144,147,148,150,151]

Treatment

Traditionally, treatment of visceral larva migrans was primarily symptomatic, especially because much of the morbidity is associated with immunopathologic responses against dying parasites. In the 1960s, thiabendazole and diethylcarbamazine were determined to be effective against migrating larvae.[149] Since then, new agents of the benzimidazole class have been claimed to be equally effective but associated with fewer drug toxicities.[145] In a comparative study with thiabendazole, albendazole 10 mg/kg/day in two divided doses for 5 days was shown to be well tolerated and less toxic.[154] Another benzimidazole, mebendazole, also may be effective when given in doses high enough to achieve significant extraintestinal levels.[133] Albendazole 400 mg twice daily for 5 days is the treatment of choice. Although anecdotal experience with albendazole and mebendazole overseas suggests that these drugs are safe in children,[134] the large doses required for the treatment of larva migrans may be associated with hepatic and other toxicities (including embryotoxicities), and they have not been approved for this purpose.

Treatment of ocular larva migrans often requires surgical management, particularly in cases associated with tractional retinal detachment.[139,153] Specific anthelmintic adjunctive chemotherapy seems to be beneficial in some cases.[140,145,153]

Prognosis

Except for patients in whom blindness develops as a consequence of retinal damage and a rare fatal case resulting from the intensity of the acute clinical reaction, most patients recover. The recovery phase may be slow, however, and may take 2 years.

Prevention

Theoretically, the disease can be prevented by elimination of dog feces from the human environment, but in practice that is no less difficult to achieve than control of human excrement disposal.

OTHER ABERRANT INFECTIONS WITH INTESTINAL NEMATODES

Baylisascaris procyonis, a parasite of raccoons, also can cause visceral larva migrans, as well as an emerging eosinophilic meningitis.[164] *Baylisascaris* infection occurs when humans accidentally ingest parasite eggs that are shed in barn lofts and attics accessible to raccoons.[148,162,163,166,168] In at least one reported human case, the infection was fatal in an infant.[166] Similar to *Toxocara* infection, *Baylisascaris* larvae within aberrant hosts cannot complete their cycle and continue their aimless migration through the tissues of these hosts. Baylisascariasis is probably more severe, owing to the propensity of the larval stages of the parasite to invade the CNS, however, along with the continued growth of the larvae during migration resulting in greater mechanical damage.[162,163] The lesions caused by the larvae are eosinophilic granulomas, which tend to be concentrated in the CNS and result in eosinophilic meningitis. The disease is characterized by a severe eosinophilic pleocytosis in the cerebrospinal fluid and nonspecific diffuse white matter lesions seen on magnetic resonance imaging.[164] Neither the frequency nor the range of severity of this infection in humans is known. Most human cases have been diagnosed at autopsy. Because baylisascariasis is so uncommon, no studies are available to evaluate different anthelmintic chemotherapy regimens systematically. Some clinicians have recommended prolonged treatments with high doses of albendazole.[162,163] Given the potential severity of infection, some investigators propose

administering postexposure prophylaxis after intimate contact with raccoon feces or soil contaminated with raccoon feces (albendazole 25 mg/kg/day orally for 20 days) as soon as possible after exposure. Prolonged albendazole treatment requires monitoring of blood cell counts and liver function.

Other, less severe aberrant infections of importance to humans are those caused by the dog hookworm, primarily *Ancylostoma braziliense*, but possibly also *Uncinaria stenocephala*.[75,162,165,176] Infection with the larvae of *A. braziliense* and *U. stenocephala* cannot be completed, and larvae remain viable and migrate in the skin (usually between the epidermis and dermis); hence the terms *cutaneous larva migrans* and *creeping eruption* are used. In North America, cutaneous larva migrans is common along the Gulf Coast and along the Atlantic seaboard.[76] It also is common in the Caribbean. Failure of these zoonotic hookworms to complete entry through the human skin may reflect differences in the hydrolytic enzymes released.[165] Infection is acquired in the same fashion as that of the human hookworms. Children who expose their whole bodies to contaminated soil may be infected at any site. Adults are most likely to have infection in the lower extremities, but plumbers in the tropics, who often must crawl beneath houses, acquire infection on the elbows and knees.

The interval from exposure to appearance of the first symptoms is approximately 2 weeks; papules 2 mm in diameter then begin to appear on the skin. Behind them usually are serpiginous, erythematous, intracutaneous tunnels. The entire area itches intensely. If left untreated, cutaneous larva migrans tends to last 2 months. Albendazole 400 mg daily for 3 days or ivermectin 200 µg/kg daily for 1 to 2 days is effective treatment when administered orally. Topical therapy with a 15 percent aqueous suspension of thiabendazole was successful in one reported series. Forty-seven of 50 patients achieved permanent cure in 2 weeks, and 2 more patients were cured after a third week of treatment.[179] Placebo-treated patients were used as controls in this study. In contrast to skin penetration of zoonotic hookworms, oral ingestion of the dog hookworm *A. caninum* results in an eosinophilic enteritis syndrome (see the earlier discussion on hookworm infection).

Rarer aberrant infections include those caused by various species of *Trichostrongylus*, *Oesophagostomum*, *Angiostrongylus*, *Capillaria*, and *Anisakis*. *Trichostrongylus* is a common parasite of many mammals, and it has been found in the small intestine of humans, mainly in Asia, Africa, and Australia. Ingestion of larvae leads to the development of adult worms in the small intestine. Whether this development results in any disease remains a moot point because infections tend to be mild and usually are associated with other helminth infections.[163] *Oesophagostomum bifurcum* is a common nematode of subhuman primates in Africa and has been reported to be a common intestinal nematode that causes nodular disease of the intestines in humans living in West Africa.[170,173] Human esophagostomiasis has been treated successfully with pyrantel pamoate.[170]

Land snails and slugs serve as intermediate hosts for *Angiostrongylus* spp. *A. cantonensis* is a cause of eosinophilic meningitis (neuroangiostrongyliasis) throughout eastern Asia and Hawaii[159,169,174,175]; *A. cantonensis* has also emerged in the mainland United States, especially on the Gulf Coast after importation of infected rats and African land snails on container ships.[161] *A. costaricensis* is a cause of mesenteric arteritis and abdominal pain in Central and South America and in Latin American immigrants to the United States.[167] The rat serves as the natural host of these parasites, which live either in the lung *(A. cantonensis)* or in mesenteric arteries *(A. costaricensis)*. The rat eats the infected mollusks and ingests the larvae, which migrate to their final destination. An incomplete infection develops in individuals who ingest either the mollusks or food contaminated by the mollusks. *A. cantonensis* infection usually is limited to the CNS and is manifested as eosinophilic meningitis.[159,169,174,175]

Signs and symptoms of neuroangiostrongyliasis include meningismus, severe headache, paresthesias, and, less commonly, cranial nerve palsies. No specific treatment is available (although anthelmintics are effective in some experimental animal models[159]), but the disease is self-limited and lasts no longer than 2 weeks. Symptomatic relief has been reported with the use of prednisone. Some investigators have reported success in treating neuroangiostrongyliasis with albendazole and prednisone, together with repeated spinal taps to decrease intracranial pressure.[164] In contrast, *A. costaricensis* infection typically is manifested as abdominal or right iliac fossa pain, fever, and eosinophilia. In children with this condition, appendicitis or Meckel diverticulum may be diagnosed.[167] High doses of mebendazole have been tried as therapy for this condition, as well as albendazole.

Capillaria philippinensis is a common parasite of water fowl in the Philippines.[158] The mode of transmission of this parasite to humans is unknown, but human cases have been reported in which 40,000 adult worms were found embedded in the crypts of the small intestine. *C. philippinensis*, similar to *S. stercoralis*, can undergo autoinfection and hyperinfection in humans.[158] No associated inflammatory reaction occurs, but flattening of villi, loss of epithelial surface area, and severe malabsorption have been reported.[158,160,178] In one series of 1000 cases of *C. philippinensis* infection, a mortality rate of 10 percent was reported.[160] Thiabendazole may be effective in shortening the course of the infection,[178] although albendazole has become the treatment of choice more recently.[158] Another member of the genus, *C. hepatica*, a rare zoonosis of humans, has been known to disseminate to the lungs, liver, and other viscera.[172]

Anisakis spp. are nematode parasites of marine mammals, with fish being intermediate hosts. When the infective larvae of the parasite are ingested as a result of eating raw or poorly cooked fish, they may become embedded in the gastric mucosa and cause eosinophilic granuloma.* In adults, the infection may resemble carcinoma of the stomach clinically and radiographically. Human anisakiasis occurs frequently in Japan, where raw marine fish are eaten commonly, and in Holland, where lightly pickled herring is considered a delicacy.

FILARIAL PARASITES

Except for rare instances of zoonotic *Brugia* infection, the filarial worms parasitizing humans affect people within the geographic area almost entirely limited to the developing world, especially sub-Saharan Africa and India. Although accurate data are lacking, approximately 115 million people are infected with lymphatic filariasis and 26 million are infected with onchocerciasis.[183] The various human parasites in this category have certain characteristics in common. They all are spread by vectors, and the adults invade and occupy the lymphatics, skin, connective tissue, or blood. They produce live embryos called *microfilariae* that enter the bloodstream or skin, where they can survive for months or years without further development. The range of disease caused by these worms is wide; some produce no symptoms, whereas others can be responsible for severe clinical disorders.

The life cycles of the filarial worms are similar in that infections are acquired through an insect bite, during which transmission is effected by introduction of infective larvae onto the skin of the host from the mouth parts of the insect. The larvae enter the wound in the skin and make their way to the respective tissue, where they mature into adult worms. The adults mate and produce live microfilariae, which, in lymphatic filariasis, migrate to the blood through the walls of the lymphatics or through the thoracic duct. To complete the life cycle, the microfilariae are ingested by blood-sucking insects, in which they undergo metamorphosis through two larval stages until they reach the third, infective stage. The interval from the infective bite to the appearance of microfilariae in the blood of the host can be 6 to 12 months.

Mass drug administration with ivermectin alone (for onchocerciasis), or ivermectin together with albendazole (for lymphatic filariasis), or diethylcarbamazine with albendazole (also for lymphatic filariasis) can reduce the microfilarial load of human populations living in endemic regions.[184] For onchocerciasis, reductions in microfilarial loads lead to reductions in chronic morbidity, with marked improvement in the serious skin manifestations of the infection and the prevention of blindness. For lymphatic filariasis, widespread implementation of mass drug administration one day may reduce transmission to the point of elimination. Such programs are currently under way in 10 countries of sub-Saharan Africa. In Egypt, five rounds of mass drug distribution already may have effectively eliminated transmission.[185] Mass drug administrations provide the core activities of several international public and private partnerships, including the Global Alliance to Eliminate Lymphatic Filariasis, the African Programme for Onchocerciasis Control, and the Onchocerciasis Elimination Program for the Americas.[181,182]

LYMPHATIC FILARIASIS: *WUCHERERIA BANCROFTI* AND *BRUGIA* SPECIES

Epidemiology

Wuchereria bancrofti is prevalent primarily between the Tropic of Cancer and the Tropic of Capricorn but also is encountered north of the Tropic of Cancer in Africa. An estimated 115 million infections exist in 80 countries worldwide, with approximately half of the infected individuals living in sub-Saharan Africa.[183,185,191] In each of its geographic locales, it has a specific anopheline, culicine, or aedine mosquito vector. In the Caribbean area, South America, Asia, East and West Africa, and Papua New Guinea, the microfilariae of this worm exhibit nocturnal periodicity; in the South Pacific, their periodicity is diurnal. *W. bancrofti* has no animal hosts.

Brugia malayi occurs in India, Malaysia, and other parts of Southeast Asia. Some strains of *B. malayi* are associated with animal reservoirs, as are certain other members of the genus *Brugia*, such as *B. timori*. In the United States, zoonotic Brugia infections caused by *B. beaveri* and *B. lepori* may infect humans but cannot develop patent infections.[182,189,190]

Pathophysiology

The pathology of lymphatic filariasis is caused principally by the adult-stage parasite, the host response, and bacterial superinfection of tissues with compromised lymphatic function. Adult worms induce lymphatic dilation that results in lymphatic dysfunction, lymphedema, and a greater susceptibility to bacterial infection. The consequent inflammation, plus that caused by host responses to dying parasites, damages the delicate lymphatic vessels further and compromises lymphatic function further. When such processes occur in the lymphatic vessels of the scrotum, hydrocele develops. Microfilaremia often is "asymptomatic" but frequently is associated with immune complex nephritis; more rarely, the microfilariae can be the target of immunologic hyperresponsiveness and result in a severe "tropical pulmonary eosinophilia" syndrome.[187]

Clinical Manifestations

Asymptomatic microfilaremia often develops in children living in endemic areas. By using highly sensitive diagnostic tests, including antigen detection and ultrasound ("dancing filarial sign"), one third of children living in endemic areas can be seen to be infected before age 5 years. Damage to the lymphatics of these young children frequently is subclinical, however.[192] With repeated exposure, these children begin to have episodes of acute adenolymphangitis, sometimes associated with fever and lymphangitis. These "filarial fevers" may reflect either an inflammatory response to dying parasites (with "retrograde" lymphangitis) or bacterial superinfection.[181] Progression to lymphedema of the upper and lower extremities, the most common sequela of chronic lymphatic filariasis, is an uncommon occurrence in children until after the age of puberty. Arthritis has also been noted as an occult manifestation of lymphatic filariasis in India.[186] Benign lymphedema has been described in a few patients in the United States with zoonotic *Brugia* infection.[182,190] Chronic, recurrent eosinophilic pneumonitis associated with wheezing, cough, chest pain,

pulmonary infiltrations, and hypereosinophilia (tropical pulmonary eosinophilia) is an IgE-mediated hypersensitivity reaction to microfilariae trapped in the lungs and, if left untreated, leads to debilitating interstitial pneumonitis.[187]

Diagnosis and Differential Diagnosis

The differential diagnosis of lymphatic obstruction in children should rule out other more likely conditions before focusing on filariasis. In older children and adults, familial lymphedema (Milroy disease) can mimic filariasis.

In endemic regions, lymphatic filariasis typically is diagnosed on the basis of appropriate clinical findings in a region with known endemicity for the disease. In young children living in endemic areas, however, early infection is largely subclinical.[192] A definitive diagnosis of lymphatic filariasis still relies on detecting adult parasites in the lymphatics through ultrasonography or by recovering microfilariae from the blood. In view of the circadian periodicity of the appearance of numerous microfilariae in blood, a specimen should be collected at the appropriate time, in many regions of the world between 10 PM and 2 AM, for microscopic examination by a staining or concentration technique. Increasingly, an immunochromatographic card test that measures specific filarial antigen is being used, especially in amicrofilaremic individuals.[181]

Treatment

New agents or drug regimens are needed that would be more effective against the adult filarial worm and at the same time elicit minimal immunopathologic damage. Currently, the major drugs used are especially effective against microfilariae. Diethylcarbamazine is the treatment of choice and typically is given in a 12-day course (6 mg/kg/day in three doses) for a total dose of 72 mg/kg. In the United States, for patients with microfilariae in the blood it is common practice to administer first small doses of 1 to 2 mg/kg (maximum of 50 to 100 mg) before beginning this regimen. One regimen includes beginning 50 mg on day 1, followed by 50 mg three times a day on day 2, 100 mg three times a day on day 3, and 6 mg/kg/d in three doses on days 4 to 14. More recently, a single dose of 6 mg/kg has been recognized to produce a similar therapeutic result (presumably following the test doses as just outlined).[181] Diethylcarbamazine is available under an investigational new drug protocol.*

Side effects of specific antifilarial therapy include allergic and febrile reactions that are caused by the inflammatory response to dying microfilariae rather than by the drug itself and that occur primarily in patients with high levels of circulating microfilariae. These systemic manifestations can be treated symptomatically with antihistamines or corticosteroids. Some of the allergic manifestations also may be avoided by administering diethylcarbamazine in a graded, stepwise manner. For patients with *Loa loa* coinfections, the presence of microfilariae presents a particular problem because high levels of microfilaremia can lead to encephalopathy after treatment with antiparasitic drugs. Diethylcarbamazine also is the treatment of choice for tropical pulmonary eosinophilia, a syndrome caused by circulating microfilariae. Ivermectin also may have a role in the medical treatment of lymphatic filariasis because it is very effective in clearing circulating microfilariae.[188] Albendazole, in high doses, is effective in killing adult worms and, in lower doses, inhibits microfilarial production, but it is not registered for use in lymphatic filariasis in the United States.[185]

The difficulty in management of filariasis by drugs is that late symptoms, such as elephantiasis, do not abate. The main usefulness of chemotherapy is in cases recognized early, before the anatomic abnormalities develop. Hydrocele can be treated surgically. Of critical importance to the management of lymphedema and elephantiasis are attention to hygiene, wearing shoes to prevent injury, and reduction of lymphostasis with exercise and elevation of the lower extremity.

The more recent discovery that *W. bancrofti* harbors bacterial endosymbionts has led to efforts to use tetracycline and related antimicrobial agents as part of the therapeutic regimen for lymphatic filariasis.[190] The therapeutic use of such regimens is under active investigation. As of this writing, the Centers for Disease Control and Prevention (see earlier discussion) and the Clinical Center of the National Institutes of Health (Bethesda, Md.) have extensive experience and expertise in the management and treatment of human filarial infections, including *W. bancrofti*, *L. loa*, and *Onchocerca volvulus* infections.

Prevention

Prevention in the past depended principally on vector control, which was unsatisfactory, primarily because of the difficulty in developing effective insecticides that also would be nontoxic to the rest of the environment. Successful experience in China has shown that large-scale chemoprophylaxis approaches to prevention are possible in endemic countries. Currently, through the Global Alliance to Eliminate Lymphatic Filariasis, the international community is directing a large-scale lymphatic filariasis control campaign on this principle. Typically, this control is being accomplished through single-dose combination of albendazole 400 mg with either ivermectin 200 µg/kg or diethylcarbamazine 6 mg/kg. On this basis, lymphatic filariasis has been eliminated in more than 20 countries and long-term targets for the global elimination of this infection have been proposed.[183-185] The finding of extensive subclinical infection among children living in endemic regions highlights the importance of targeting this group for MDA as well as adults.[192]

LOA LOA

L. loa infection is limited to a small area of western and central Africa and is spread by *Chrysops* flies. Periodicity

*From the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, Ga., 30333; 404-639-3670 (evenings, weekends, or holidays: 770-488-7100).

in *L. loa* microfilariae is diurnal. The parasite elicits numerous allergic inflammatory responses that are most evident in expatriates.[193,194] Infection leads to high eosinophilia and recurrent angioedema, which when localized develop into painful, pruritic, subcutaneous swellings on the extremities and the face known as Calabar swellings. Rarely, some cases of lymphatic obstruction of the lower extremities and hydroceles have been reported.

The most dramatic manifestation of this infection is the occasional appearance of a migrating *L. loa* adult under the conjunctiva of the eye. It does not damage the eye and can be removed surgically. Treatment with diethylcarbamazine, as indicated earlier, effectively destroys the adults, but reactions may be more intense than in the treatment of *Wuchereria* and *Brugia* infections. Diethylcarbamazine should be administered in a gradual, stepwise manner as described earlier, particularly in patients with high levels of circulating microfilariae. The recommended dose is higher than that used for lymphatic filariasis (9 mg/kg/d in three doses for 12 days). Coadministration of corticosteroids often is required during treatment. Encephalopathy has been described in patients receiving diethylcarbamazine, especially when heavily infected.[193] Ivermectin elicits fewer inflammatory symptoms during treatment and may be less toxic in general, but encephalopathy still can occur in patients with heavy *Loa* infections.[195] Because of the risk for encephalopathy, patients with loasis should be treated in consultation with an expert in this infection. Approaches to treatment may include plasmapheresis or a single 50-mg dose of diethylcarbamazine as for lymphatic filariasis (see earlier), gradually building to the final dose of 9 mg/kg/day over 2 weeks.

ONCHOCERCA VOLVULUS

Onchocerca volvulus infection is acquired through the bite of a *Simulium* fly, which tends to breed along rivers and streams (hence the name of the disease "river blindness").

Epidemiology

Disease is limited to sub-Saharan Africa, where approximately 99 percent of the world's 26 million cases occur (approximately half of the cases occur in Nigeria and Congo),[183] and focal pockets in Central America (primarily Guatemala and Chiapas State, Mexico), and the northern parts of South America (near the border between Venezuela and Brazil and in Ecuador). In view of human dependence on water and the establishment of settlements along rivers, the frequency of infection tends to be high in areas where *Simulium* prevails. The development of hydroelectric power based on the construction of large dams can increase the breeding sites of *Simulium* and increase the incidence of *Onchocerca* infection.

Pathophysiology

Larvae deposited by a *Simulium* bite remain in the subcutaneous tissue and develop into adult worms there. Adult worms tend to become coiled, and worms of both sexes become enveloped by fibrous tissue and form nodules within which they reproduce. The larvae produced by fertilized females invade the skin, where they remain until they are picked up by a *Simulium* bite, or they die about 30 months later. In addition to the skin, microfilariae penetrate the eye and affect every layer from the conjunctiva to the optic nerve. In African onchocerciasis, chorioretinitis and optic atrophy occur commonly; in the Central American disease, iritis is the primary lesion.

The probability of the development of eye disease is related to the location of the adult worms. When the nodules are situated around the head, eye lesions are common; when they are in the lower parts of the body, eye lesions occur less frequently. In Africa, the nodules tend to be distributed primarily in the lower parts of the body, but because of the high prevalence of the infection, onchocercal blindness is common. In Central America, the lesions tend to be on the upper part of the body.

Clinical Manifestations

The appearance of the skin nodules and the presence of live microfilariae within the eye (readily seen with a slit-lamp ophthalmoscopic examination) are the manifestations of early and intermediate disease. Later, the eye involvement includes keratitis, iridocyclitis, chorioretinitis, and, eventually, blindness. Microfilariae in the skin cause an inflammatory reaction that includes acute papular onchodermatitis and chronic changes such as edema, lichenification, atrophy, and depigmentation.[191]

Diagnosis and Differential Diagnosis

Because the skin invasion is associated with itching, the pruritus of onchocercal infection must be differentiated from contact dermatitis, prickly heat, insect bites, and scabies. Onchocerciasis is identified by examination of a skin snip. Examination of sectioned and stained tissue or a stained impression smear reveals microfilariae.

Treatment

Surgical removal of all visible nodules may radically extirpate the source of new microfilariae that invade the eye. The routine use of nodulectomy is still controversial, however. Chemotherapy with ivermectin (single oral dose of 150 μg/kg administered every 6 to 12 months) until asymptomatic is the treatment of choice. Ivermectin reduces the number of microfilariae in the skin within days, and subsequently the number of microfilariae in the eye, and prevents the onset of blindness.[196] Ivermectin also can be used in mass treatment to diminish transmission by the vector and control the incidence of this infection.[183,184,196,197] Diethylcarbamazine is contraindicated for patients with onchocerciasis because it can lead to severe allergic symptoms, a condition sometimes known as the Mazzotti reaction.

Prevention

Today the mainstay of river blindness control is MDA with ivermectin, which has recently led to the elimination

of onchocerciasis in Mali and Senegal and will soon lead to elimination of the disease in the six remaining Latin American countries.[183]

MANSONELLA PERSTANS AND *MANSONELLA OZZARDI*

Neither *Mansonella perstans* nor *Mansonella ozzardi* is known to cause significant human pathology, but the microfilariae present in blood must be distinguished morphologically from the microfilariae of the other more pathogenic filariae. *M. ozzardi* is found throughout the Caribbean (especially Haiti) and Central America. It has been suggested as a cause of chronic arthritis in these regions. *M. perstans* also is found in Africa, where it has been identified as a cause of painless nodules in the conjunctiva and secondary eyelid swelling. For that reason, it sometimes is called the Kampala or Ugandan eye worm.[198] Albendazole or mebendazole is the treatment of choice for *M. perstans* infection.

DIROFILARIA IMMITIS

Dirofilaria immitis is a filarial worm commonly found in dogs, in which it occupies the right ventricle of the heart. The microfilariae produced circulate in blood and are transmitted to new animals through the bite of culicine mosquitoes. Fewer than 100 cases of human infection have been reported, none of them in children. Most human hosts infected with *Dirofilaria* were asymptomatic, but individuals who had symptoms complained of chest pain, wheezing, and cough. All infected individuals had coin lesions detected on pulmonary radiographs.[199,200] Human infection is transmitted through a mosquito bite. As with visceral larva migrans and the zoonotic *Brugia* infections, *D. immitis* cannot complete its life cycle in humans. No microfilariae of this worm have ever been shown in human peripheral blood.

All patients evaluated for pulmonary dirofilariasis have had mild peripheral eosinophilia, usually not exceeding 10 percent. Because the radiographic picture is not diagnostic, and in view of the potential seriousness of a coin lesion,[199] the lesion must be examined histologically. If a worm is found, the diagnosis of dirofilariasis can be made; if it is not found, the diagnosis is still tenable. In the presence of eosinophilia and pneumonitis, however, a whole range of other diagnostic possibilities must be considered, including eosinophilic pneumonia, polyarteritis nodosa, Wegener granulomatosis, and histiocytosis X. No treatment is necessary for this infection in humans.

DRACUNCULUS MEDINENSIS

Infection by *Dracunculus medinensis* (guinea worm) is limited largely to sub-Saharan Africa. As of this writing in 2011, only 1,008 cases are believed to remain worldwide, with almost all of the cases in Sudan or South Sudan. Ten or fewer cases remain in Mali, Chad, and Ethiopia, respectively.[201]

Because filtering of drinking water can prevent this infection effectively, authorities from the World Health Organization and the Carter Center are optimistic that this parasite will soon be eradicated through appropriate control measures.[183]

SUBSECTION 3 *CESTODES*

CHAPTER 226

Cestodes

A. Clinton White, Jr. • Philip R. Fischer • Pedro Legua

OVERVIEW OF CESTODES AND THEIR IMPORTANCE FOR CHILDREN

Cestodes are multicellular helminth parasites.[234] Children may harbor the adult worms (tapeworms) or larval stages (e.g., cysticercosis or hydatid disease). The adult tapeworms are segmented worms that contain a scolex (attachment organ); a neck region, where the segments are formed; and segments termed *proglottids*. The scolex contains either sucking grooves (*Diphyllobothrium* and *Spirometra*) or round suckers (other species). In some species (e.g., *Taenia solium*), the scolex is armed with rows of hooks, which also aids in attachment. The proglottids develop in the neck region and move distally as they are displaced by newer proglottids. Eventually, chains of proglottids form and compose the body of the adult worm. The external surface of the proglottid forms an absorptive surface that functions as the parasite gut. As the proglottids are displaced from the scolex, they gradually mature, with both male and female sexual organs developing in each proglottid. The terminal proglottids contain the uterus, which are full of ova. The ova of *Spirometra* and *Diphyllobothrium* are shed into water, where they infect a series of aquatic intermediate hosts. The ova of other species infect the immediate host after being ingested. Both larval and adult forms of *Hymenolepis nana* live in the human intestines, and the entire life cycle can take place in a single host. Humans are dead-end hosts for numerous zoonotic tapeworms, including *T. solium* (cysticercosis), *Echinococcus* spp. (hydatid disease), and *Spirometra* (sparganosis). The term *cysticercosis* (literally, "bladder-tail") refers to infection of tissues with an intermediate form of the parasite containing a cystic parasite with one (or a small number of) invaginated scolex. Human cysticercosis usually is caused by *T. solium*. However, human cysticercosis is also rarely caused by *Taenia crassiceps* or *Taenia multiceps*. *Hydatid disease* refers to infection of tissues with the intermediate form of the parasites of the genus *Echinococcus*, which form cystic lesions filled with innumerable protoscolices, each of which can turn into a tapeworm or another hydatid lesion, depending on the tissues. Infections with cestodes have been common human infections since antiquity and have been found in mummies.[20,101] Currently, approximately 200 million people worldwide are infected by cestodes.

TAENIA SAGINATA (BEEF TAPEWORM) INFECTION

The different life cycle forms and designation of species of the beef tapeworm were identified in the 18th and 19th centuries.[259] Although other species names have been used in the past, *Taenia saginata* is accepted now as an inclusive term for all of the species of tapeworms acquired from beef. In recent years, however, *Taenia asiatica* has been identified as a distinct species similar to *T. saginata* but acquired from pork. Differentiation of these species morphologically, however, is difficult, and identification of species is aided by DNA analysis.[37,101]

The Organism

The scolex of *T. saginata* measures 1 to 2 mm in diameter and has four muscular suckers but bears no hooks. The length of the parasite usually varies from 4 to 10 m but may reach 25 m. The size of the proglottids depends on their stage of development and their state of muscular relaxation. Gravid proglottids typically are 16 to 20 mm in length and 5 to 7 mm in width. The linear, central uterine stem has 12 to 30 main lateral branches on each side. The eggs measure 30 to 40 μm in diameter. The six-hooked embryo is surrounded by a brown, radially striated embryophore. When the bovine host ingests the ova, embryos hatch and burrow through the intestinal mucosa, where they gain access to the circulation. After lodging in capillaries, the embryo develops into a larval cysticercus. This cystic, ovoid structure measures 7 to 10 mm × 4 to 6 mm and contains an invaginated scolex.

Cattle are the principal intermediate hosts. Humans are the only definitive host. Ingestion of *T. saginata* eggs is of no particular danger to children because humans are not susceptible to development of the cysticercus stage.

Transmission

The life cycle of *T. saginata* requires transmission of the infection to the intermediate host and subsequently to humans, who in turn transmit the organism to other intermediate hosts. Contamination of pastures or feed lots with human feces or untreated sewage leads to bovine cysticercosis. When humans ingest raw or poorly cooked beef containing viable cysticerci, the scolex evaginates

from the cysticercus and attaches to the intestinal wall. Proglottids develop from the neck region and gradually enlarge to form the adult tapeworm. Gravid proglottids, which are at the distal end of the worm, appear only 84 to 120 days after infection.[236] Infection may persist for years. In most geographic areas, parasitism is with a single worm, but in highly endemic areas, multiple infections may be found.[236]

Ova may be found within feces. However, eggs are shed more frequently when gravid proglottids actively migrate from the anus. As these muscular proglottids crawl about, eggs are expressed from the anterior margin. The ova of *T. solium* and *T. saginata* are not distinguishable on morphologic grounds.

Epidemiology

Worldwide, 45 to 60 million people are thought to be infected with *T. saginata*. Infection is most important in tropical and subtropical cattle-raising areas of Africa, the Middle East, Europe, Asia, and South America.[37,130,143] The prevalence of human taeniasis caused by *T. saginata* is poorly understood. In general, the prevalence of human infections is less than 1 percent of stool examinations in all but highly endemic areas, but because of the poor sensitivity of the assays, this figure may understate the prevalence. In recent studies, prevalence rates of more than 20 percent have been noted in East Africa, Bali, and Tibet.[40] Although the incidence of taeniasis in the United States is low, transmission does occur. However, less than 0.1 percent of fecal specimens examined in state health laboratories were positive for *Taenia* eggs.[116] With socioeconomic changes, improvements in the cattle industry, and decreasing instances of ingestion of undercooked beef, the prevalence of intestinal taeniasis likely will continue to drop in much of the world.

Pathology and Pathogenesis

Little is known of the pathology or pathogenesis of intestinal taeniasis. Speculation about local mucosal trauma, irritation, production of toxic substances, or induction of clinically significant hypersensitivity has scant documentation. Rare, ectopic localization of worms or proglottids may stimulate local inflammatory reactions. Because adult worms "rob" the infected host of nutrients, malnutrition could result from the child's incomplete uptake of ingested food, but little evidence exists to support this possibility.

Clinical Manifestations

A variety of symptoms have been attributed to *T. saginata*, but the parasite infection likely is often merely coincidental to the concurrently observed symptoms in the child.[37] The most common complaint is the discomfort caused by the migration of gravid proglottids from the anus. The patient's awareness of the infection frequently causes a preoccupation with gastrointestinal function. Some studies of *T. saginata* infection revealed abdominal pain, nausea, weakness, and loss of weight as the most common symptoms recorded.[37,39,259] Alterations in appetite and bowel habits were reported inconsistently. Intestinal obstruction and symptoms related to ectopic localization of proglottids are extremely rare. Although taeniasis usually is not associated with significant eosinophilia, some patients occasionally have significant eosinophilia between the sixth and ninth weeks after the initial infection occurs. One study reported that by the time the patients first began passing proglottids, the eosinophil counts had returned to normal or nearly normal.[87] Another series of observations showed a syndrome of marked eosinophilia and severe colicky abdominal pain that occurred approximately 1 month before the patients passed *Taenia* proglottids.[9] A single experimental infection produced symptoms of nausea, headache, and disturbed sleep at approximately the time that gravid proglottids appeared in the stool, 84 days after infection. A 10.5 percent increase in the number of eosinophils and a 13 percent increase in the number of lymphocytes were noted.[236]

Diagnosis

The scolex of *T. saginata* lacks hooks and is differentiated easily from the scolex of *T. solium*, which bears a circle of hooks. However, the scolex usually is not recovered, even after successful treatment. Studies suggest that use of polyethylene glycol salts as a purgative may improve recovery of proglottids.[114] Eggs may be seen on routine fecal wet mounts, but the likelihood of their being detected is enhanced by concentration methods. Even then, ova are shed only intermittently, and the yield of a single stool examination is low. Cellulose tape swabs applied to the anal and perianal skin, as used for the diagnosis of *Enterobius* infection, have been found to be even more efficient than fecal concentration.[241]

The eggs of *T. saginata* and *T. solium* cannot be differentiated morphologically. Thus, examination of gravid proglottids is the usual method for determining species. The patient is instructed to collect proglottids in a vial of saline and to deliver the specimen to the laboratory as soon as possible. Fixatives such as alcohol and formalin tend to render the proglottids rigid and opaque. The proglottid should be compressed between two microscope slides. If the uterus contains enough ova, counting the main branches of the uterine stem is relatively easy. The uterus is more readily identified by injecting a small amount of India ink into the midportion. A count of 13 or fewer branches on one side of the stem is considered diagnostic for *T. solium*. If the count is 14 or more, the species is designated *T. saginata*. Because of morphologic variations, this method has been criticized, particularly when the decision is based on gravid proglottids with counts in the range of 12 to 15. Analysis of many specimens of *Taenia*, as identified by their scolex, showed that mature proglottids with fully developed sex organs could be differentiated by several characteristics. The most prominent features are a vaginal sphincter seen only in *T. saginata* and a third ovarian lobe that is present only in *T. solium*. To define these and other features, the proglottids require painstaking staining and clearing as well as examination by a skilled parasitologist.

Antigen detection tests are becoming increasingly useful for the identification of *T. saginata*. Tests for *T.*

solium currently are more specific than tests for *T. saginata*.[2] Polymerase chain reaction (PCR) testing has been useful in diagnosis of *T. saginata* in field situations.[37] On occasion, the diagnosis of tapeworm is established when larger portions of a worm appear as a ribbon-like defect in the barium column during contrast studies of the gastrointestinal tract. In plain films of the abdomen, a tapeworm may be seen as a linear density in a gas-filled loop of bowel.

Treatment

Praziquantel, a pyrazinoisoquinoline derivative, is the primary medication used to treat *T. saginata*. It is given as a single oral dose of 5 to 10 mg/kg. An alternative to praziquantel for treatment of intestinal taeniasis is niclosamide (marketed as Yomesan in parts of Europe but not consistently available in the United States), which is given as a single oral dose of 50 mg/kg (up to 2 g for large children or for adults). Nitazoxanide, a thiazolide agent approved for use in children with other parasitic infections, has been effective in treating taeniasis that has been incompletely responsive to both praziquantel and niclosamide.[130]

Because infection with *T. saginata* is not contagious, no routine follow-up is needed after treatment. If, however, proglottids are noted through the anus or in the stool more than a week after treatment is completed, subsequent therapy may be considered, perhaps with an alternative agent.

Prognosis

Symptoms, when present, may be annoying but do not usually alter health significantly. Treatment is highly effective, and the prognosis is excellent.

Prevention

T. saginata infection can be prevented by avoiding the ingestion of raw or undercooked beef. In addition, visual meat inspection is effective in detecting all but light infections. Cooking beef to a temperature of 56°C (133°F) kills cysticerci. Education of workers in the cattle-raising industry, coupled with detection and prompt treatment of human infection, may reduce the incidence of transmission. Vaccines to prevent bovine *T. saginata* cysticercosis are feasible, but development has been slowed by limited commercial interest.[138]

TAENIA ASIATICA (ASIAN PORK TAPEWORM)

T. asiatica was identified in East and Southeast Asia, where humans become infected by eating small cysts contained in raw porcine liver. The proglottids are morphologically similar to those of *T. saginata*, such that it was not recognized as a separate species until 1993.[37,109]

The Organism

Although adult tapeworm proglottids of *T. asiatica* are morphologically similar to those of *T. saginata*, the scolex contains a rostellum (like *T. solium*) but no hooks (like *T. saginata*). Proglottids usually contain 16 to 21 uterine branches, similar to *T. saginata*. The larval cysticercus stage is also similar to that of *T. saginata*, but the cysticerci generally are smaller. The cysticerci also are located primarily in the liver, not generally in muscle. *T. asiatica* cysticerci are found mainly in pigs but have been identified in cattle, goats, monkeys, and wild boar.[109]

Transmission

Pigs (and also cattle, wild boar, and goats) become infected by ingesting *T. asiatica* eggs, which hatch, releasing the larvae, which in turn invade and develop into the cysticercal stage primarily in the liver. Animals, including humans, become infected when they ingest cysticerci (usually in raw porcine liver) and then develop the intestinal adult forms of infection. An experimental human infection demonstrated that a period of 76 days transpired between ingestion of the cysticercus and the appearance of gravid proglottids.[61]

Epidemiology

Asian taeniasis has been identified in Taiwan, Korea, China, Philippines, Vietnam, Thailand, Indonesia, and Malaysia.[37,61] It may be that other parts of the Asia-Pacific region also are endemic for *T. asiatica* but that previous surveys incorrectly identified the offending organism as *T. saginata*. The prevalence of infection varies among regions, probably related to religious and cultural choices about food; 0 to 21 percent of people in various parts of Indonesia are infected.[254]

Pathology and Pathogenesis

Observations in humans and studies in mice suggest that the pathogenesis of infection by *T. asiatica* is similar to that of *T. saginata*.[110] No human cysticercal form has been identified.

Clinical Manifestations, Diagnosis, Treatment, and Prognosis

The clinical manifestations, diagnosis, treatment, and prognosis of *T. asiatica* have not been described completely, but they appear to be similar or identical to those of *T. saginata*.

Prevention

Human *T. asiatica* infection can be prevented by avoiding ingestion of undercooked liver and other viscera (especially porcine).

TAENIA SOLIUM

Cysticercosis was first described in ancient Greece, where cysticerci were noted in infected pork.[70] The life cycle was clarified by the 19th century. The main clinical manifestation results from infection of the central nervous system (CNS) and is termed *neurocysticercosis*. Large case

series describing most of the clinical manifestations were published in the early 20th century.[52] Neurocysticercosis, however, was diagnosed only rarely until the late 1970s. Subsequent advances in neuroimaging led to a dramatic increase in recognition.[191] Neurocysticercosis is now recognized as among the more common causes of neurologic disease worldwide.*

The Organism

T. solium, referred to as the pork tapeworm, takes two distinct forms in the human host: taeniasis (tapeworm infection of the gut lumen) and cysticercosis (infection of tissues with the larval cysticercus form).[70] Neurocysticercosis refers to cysticercosis involving the CNS (including the subarachnoid space, spinal cord, and eyes). Humans develop the adult tapeworm after ingesting undercooked pork containing the cysticercus. The scolex evaginates in the intestines, attaches, and develops chains of proglottids. The tapeworms can be several meters long. Eggs and gravid proglottids are shed intermittently into stool. The off-white proglottids appear as flattened segments 1 mm thick and up to 2 cm in length and 1 cm in width. Pigs are infected after ingesting eggs or proglottids from human fecal material. Once ingested, the larval oncospheres emerge from the eggs, penetrate the wall of the gut, enter the bloodstream, and migrate to the tissues, where they develop into cysticerci during a period of a few weeks.

Transmission

Field studies of both taeniasis and cysticercosis are associated with tight clustering.† Taeniasis is acquired by ingestion of undercooked pork and is closely tied to pig-raising areas in endemic countries. Most carriers are from families that raise pigs and butcher them informally in the household. Cysticercosis is acquired from the human tapeworm carriers, who not only shed eggs into the environment but also harbor eggs on their hands and fingernails. These eggs can then autoinfect the tapeworm carrier or infect other people. Thus, most transmission occurs among close contacts of tapeworm carriers. Human cysticercosis is not always acquired directly from pork, as illustrated by outbreaks noted among vegetarians in India and orthodox Jews in the United States.[207,217,251] In both cases, transmission has been associated with domestic servants who were tapeworm carriers, a factor also seen in urban areas lacking infected pigs.[103]

Epidemiology

The global prevalence of human cysticercosis is not clearly defined. Between 50 and 100 million people are thought to be infected with cysticercosis, but far fewer with intestinal taeniasis.[22,36,164] Nearly all areas where pigs are raised that have access to human fecal material are endemic for cysticercosis.[70] In endemic areas, pigs often are reared on small farms, where they are allowed to forage for food rather than being fed. Improved sanitation, meat inspection, and animal husbandry led to the eradication of cysticercosis from western Europe, which previously was highly endemic. However, similar approaches have not proved sustainable in poorer countries. Currently, porcine cysticercosis remains highly endemic in Latin America, sub-Saharan Africa, and South and Southeast Asia, as well as parts of Korea, China, Indonesia, and Papua New Guinea.[109,165]

In the United States, porcine cysticercosis is a very rare occurrence. In contrast, human neurocysticercosis is widespread among immigrants from endemic countries.* Limited transmission occurs in the United States, mainly linked to tapeworm carriers infected in endemic areas.[42,167,212,229]

Pathology and Pathogenesis

Cysticerci can develop in a wide range of tissues. In most tissues, the cysticerci cause few symptoms and their survival appears to be limited. For example, many of those infected have cigar-shaped calcifications noted on radiographs of skeletal muscle, despite the absence of musculoskeletal symptoms. By contrast, infection of the CNS often lasts for years and can cause severe symptoms.

Cysticerci mature to their full size (typically 10 to 20 mm in diameter) within a few weeks after infection occurs, but as illustrated in studies of British subjects returning from India and Hispanic immigrants to the United States, symptoms do not develop for several years.[50,52] This delay may reflect the parasites' complex array of molecules used to modulate the host inflammatory response.[70] When the parasites lose the ability to evade immune attack, the cysticerci are attacked by a granulomatous response with a mixed cell population, including lymphocytes and mononuclear cells, with variable numbers of eosinophils and neutrophils.† This granulomatous host response to the parasite, when it is present in the brain parenchyma, is thought to be the cause of seizures, the characteristic clinical feature of parenchymal neurocysticercosis.[232] During the course of several months, the inflamed parasite is invaded by inflammatory cells, the cyst cavity collapses, and the parasite material is replaced by the host granulomatous response.[96] The lesion eventually either resolves or is replaced by a small calcified granuloma. The calcified lesions contain a mixture of fibrosis and residual parasitic debris. An inflammatory response to persistent parasitic antigen may be the cause of recurrent seizures in patients with cerebral calcifications. Rarely, massive infection is accompanied by a diffuse cerebral edema.[186,240]

Extraparenchymal neurocysticercosis is associated with a poorer prognosis, largely because of production of hydrocephalus.[70,72] Parasites can cause obstructive hydrocephalus by lodging in the outflow tracks of the cerebral ventricles. Cysticerci in the basilar cisterns often are associated with chronic arachnoiditis. This basilar inflammation may lead to chronic meningitis (with headache and

nuchal rigidity but usually without fever), vasculitis and strokes, or communicating hydrocephalus. Less frequently, cysticerci in fissures enlarge to 5 cm or larger (termed giant cysticerci). The parasites, along with accompanying cerebral edema, may cause a mass effect. In patients with multiple cysticerci, several forms of the disease can be present at the same time.

Clinical Manifestations

Taeniasis

Taeniasis typically causes few symptoms. Cases have been associated with vague abdominal complaints and occasionally pruritus. The most specific symptom is the passage of proglottids in the stool. The proglottids appear flattened (typically 0.3 to 0.5 cm wide × 1 to 2 cm long and 1 mm thick). Each segment has 13 or fewer uterine branches. Unlike *T. saginata*, the proglottids usually are single and seldom are noted to be motile.

Cysticercosis

The clinical manifestations of cysticercosis are extremely variable, depending on the location of the parasites and the host inflammatory response. Experts now group neurocysticercosis into a range of syndromes that differ in pathogenesis, clinical manifestations, prognosis, and management.*

Single Enhancing Lesions. The most common presentation in children with neurocysticercosis is with seizures and a single enhancing lesion on neuroimaging studies.† Onset typically occurs in those 5 to 40 years of age, but it has been noted in infants. Most cases are manifested with seizures, which can be isolated or recurrent. The seizures typically are focal with secondary generalization, although they may be focal or generalized.[220,251] Some children experience only severe headaches,[180] which can resemble either tension headaches or migraines. Imaging studies of children reveal either a focal area of enhancement or a ring of enhancing lesions, often with surrounding edema. Lesions typically are found within the cortex.

Multiple Cystic (Viable) Lesions. Similar to children with single enhancing lesions, patients with multiple parenchymal cysticerci also have seizures. The seizures more often are generalized or focal with secondary generalization but also may be focal.[26,49,82,222] Neuroimaging studies demonstrate edema, contrast enhancement, or both for one or more parasites, and symptoms are thought to result from the host inflammatory response. Noninflamed cysts cause few symptoms, even when they are numerous,[71] but they pose a risk for development of recurrent symptoms when they degenerate.

Other symptoms include headaches. Infected children may develop learning disabilities,[33,134,193,198,253] but in many cases they may be the result of either poorly controlled seizures or hydrocephalus.[235] An association of cysticercosis with depression and occasionally psychotic episodes also may exist.[67]

Cysticercal Encephalitis. Some children have diffuse cerebral edema from large numbers of inflamed cysticerci, termed *cysticercal encephalitis.* The clinical presentation includes signs or symptoms of raised intracranial pressure, seizures, and altered mental status.[186,240] Cysticercal encephalitis is thought to result from a brisk inflammatory response to a massive infection and is seen more frequently in children and women than in adult men. This pathogenesis is the direct result of the host inflammatory response, and the key to management is to address inflammatory and cerebral edema. Antiparasitic drugs are contraindicated because they can worsen the cerebral edema.

Parenchymal Calcifications. Resolution of neurocysticercosis can be associated with the formation of calcified granulomata within the brain parenchyma.[160] The calcifications appear as well-defined calcified nodules measuring 2 to 10 mm. The calcified lesions contain fibrotic reactions, parasite debris, and calcium deposits, with variable degrees of inflammation. Patients frequently present with seizures.[159-161,219] The most common imaging finding from neurocysticercosis in population-based studies in endemic villages is with focal calcifications.[48,65,155,184] Few patients will have focal abnormalities on electroencephalographic studies.[28] Among patients with seizures, calcified lesions are a risk factor for having recurrent seizures.[24,85,161,183] Patients with seizures and calcifications should be treated with antiepileptic therapy indefinitely. About half of patients with calcified neurocysticercosis and seizures have associated enhancement and edema on magnetic resonance imaging (MRI) studies.[161] Rather than revealing viable parasites, the enhancement may result from breakdown of the calcified granulomata, with release of antigen resulting in restimulation of the host inflammation.[95,161]

Ventricular Neurocysticercosis. Approximately 10 to 20 percent of adult patients with cysticercosis have cysticerci in the ventricles,* but the numbers often are lower in children.[202] Cysticerci are found in any of the ventricles, but symptoms are particularly associated with obstruction of the outflow of the third or fourth ventricle at the cerebral aqueduct or foramina of Luschka and Magendie. In contrast to parenchymal disease that largely results from the host inflammatory response, symptoms of ventricular disease result from mechanical obstruction typically caused by viable parasites.[119] Within the thin-walled viable cysticerci, the cyst fluid often is isodense with cerebrospinal fluid (CSF), rendering them difficult to detect. Computed tomography (CT) scanning may show only obstructive hydrocephalus or distortion of the shapes of the involved ventricle. Even on MRI, the findings may be subtle and can be missed by inexperienced observers unless the patients have concomitant parenchymal cysticerci.[98,263,265]

*References 70, 72, 73, 160, 162, 213.
†References 78, 197, 198, 202, 213, 218, 251.

*References 70,72,162,187,203,212.

Symptoms from ventricular neurocysticercosis usually result from raised intracranial pressure and include headache, nausea or vomiting, altered mental status, papilledema with visual changes, or dizziness. The onset is extremely variable from chronic intermittent headache to sudden loss of consciousness.

Subarachnoid Cysticercosis. Subarachnoid cysticercosis can also be quite variable. Small cysticerci in the gyri have a clinical presentation and prognosis similar to that of parenchymal cysts, although they are associated more often with CSF pleocytosis, may be slightly larger, and respond less well to antiparasitic drugs.[70,203] Cysticerci in the basilar cistern can cause arachnoiditis, leading to CSF outflow obstruction, communicating hydrocephalus, vasculitis, and strokes.[70,230] In the era before antiparasitic drugs were available, this form carried a high case-fatality rate.[230] By contrast, more recent case series have been characterized by low mortality rates.[36,43,162,187,212]

Most patients with cysticerci in the basilar cisterns are infected with large numbers of parasites, and they frequently have coexisting ventricular or parenchymal as well as subarachnoid disease. Symptomatic cysticerci in the basilar cisterns typically are accompanied by chronic arachnoiditis. This arachnoiditis may present as meningitis with headache, stiff neck, and CSF pleocytosis, but it usually is not accompanied by fever. Patients often develop communicating hydrocephalus (headaches, nausea, vomiting, and dizziness). Basilar cysticercosis frequently involves the basilar vasculature either by direct invasion or by inducing vasculitis. Thus, patients may present with cerebrovascular accidents, which may involve either small vessels with lacunar infarctions from vasculitis or large-vessel strokes (associated with invasion of the vessel wall by the parasite).[11,44,72] Some patients present with intracerebral hemorrhages.[252]

Giant Cysticerci. Cysticerci, termed giant cysticerci, can develop in the fissures (especially the sylvian fissure) and may enlarge to more than 5 cm in diameter.[175] In some cases, the cysticerci can lose the scolex and may grow as clusters of cyst walls (termed racemose cysticercosis). Giant cysticerci not only are associated with symptoms of parenchymal inflammation but also can cause mass effects such as midline shift. Frequently, giant cysticerci are accompanied by cysticerci in the parenchyma or basilar cisterns. Giant cysticerci are readily visualized by CT or MRI, but the accompanying basilar cysticerci may not be seen as easily.

Other Forms of Cysticercosis. Neurocysticercosis rarely is limited to the spine, but spinal disease is common with subarachnoid disease.[25] Most patients present with radicular pain and, less frequently, myelitis. In most cases, cysticerci are in the spinal fluid, but they also can be intramedullary cysticerci.[132] The intramedullary form typically presents with myelitis. Orbital involvement includes subconjunctival cysticerci and involvement of the extraocular muscles.[179,211] Intraocular disease may be subretinal, intravitreal, or within the anterior chamber. Skeletal muscle involvement typically is asymptomatic, but it may result in pseudohypertrophy or weakness with massive infection. Subcutaneous lesions typically present as one or more painless mobile cystic lesions. Subcutaneous disease is more commonly noted in Asia and Africa than in the Western Hemisphere.

Diagnosis

Taeniasis

Taeniasis has been diagnosed traditionally by examination of the stool for proglottids, ova, or both. The ova and proglottids are shed only intermittently, and collection of stool specimens from children can prove difficult. Furthermore, the sensitivity of stool microscopy for ova is only 26 percent,[4] and the ova of *T. solium* and *T. saginata* are indistinguishable, which limits the specificity of the assay. Identification of species requires collection of the proglottids, which can be facilitated by treating the patient with polyethylene glycol.[114] The proglottids of the two species can be distinguished by counting the number of uterine branches, which are lower for *T. solium*.

More sensitive and specific techniques are available only as research tools. Antigen-detection assays have a specificity of 99.2 percent and a sensitivity of 70 to 92 percent,[3,4,195] but most cannot distinguish *Taenia* spp. Enzyme-linked immunosorbent assay (ELISA) to identify serum antibodies to *T. solium* tapeworm-stage antigens may be more sensitive than are stool-based tests and seem to be specific for the *T. solium* tapeworm stage.[97,135] However, the antibody may persist after treatment. PCR also can be used to improve sensitivity and specificity.[148]

Neurocysticercosis

Establishing the diagnosis of neurocysticercosis is more difficult than with many other parasitic infections. The major clinical presentations are nonspecific, and the location of the parasites within the CNS usually precludes their being observed directly. Serologic tests using crude antigens (including a number of commercially available ELISAs) are plagued by poor sensitivity and specificity. However, computerized imaging methods (e.g., CT and MRI) have led to a dramatic increase in the ability to recognize cases and are now the mainstay of diagnosis (Figs. 226-1 to 226-3), although even these techniques cannot always distinguish neurocysticercosis from other neurologic processes.

An expert group proposed diagnostic criteria based on neuroimaging studies, serologic tests, clinical history, and exposure.[46] The presence of either a single absolute criterion or two major criteria along with two minor or epidemiologic criteria is considered diagnostic. One major criterion plus two other criteria or three minor criteria along with exposure define a probable diagnosis.

Direct visualization of the parasite on ophthalmoscopic examination or histology is considered diagnostic of neurocysticercosis.[46] However, biopsy or autopsy material demonstrating *T. solium* parasites rarely is available, and parasites seldom are visualized in the eye. The

neuroimaging pattern of a cystic lesion with a mural nodule measuring 1 to 3 mm (consistent with a scolex) is thought to be pathognomonic for cysticercosis.[263,264] However, rare cases have been reported in which similar findings have been noted in other diseases, and even in neurocysticercosis, the scolex cannot be visualized in most cases.

The main major diagnostic criterion for neurocysticercosis is one or more lesions on neuroimaging studies highly suggestive of neurocysticercosis.[45,46] Viable cysticerci appear on CT or MRI scans as rounded fluid collections typically 1 to 2 cm in diameter. The cyst fluid is isodense with CSF (hypodense in contrast to brain tissue on CT or T1 imaging). The scolex sometimes is visible as a small nodule found attached to the cyst wall. The wall of the cysticercus initially is isodense with the parenchyma and not easily visualized. On T2-weighted and fluid attenuated inversion recovery images, the fluid is seen as hyperintense. Inflamed cysticerci are characterized by perilesional edema and contrast enhancement.[232] Subsequently, the cyst fluid increases in density and becomes infiltrated by host inflammatory cells. The cyst cavity eventually collapses, forming a solid area of focal enhancement. At that point, the granulomatous inflammation either resolves or leads to the formation of a calcified nodule typically measuring 2 to 6 mm in diameter.

Although enhancing lesions are typical of neurocysticercosis, similar lesions can be noted with tuberculomas,

brain abscesses, and tumors. Rajshekhar and Chandy[182] noted that cysticercal lesions typically have a diameter smaller than 20 mm and rarely cause midline shift. A single, round, enhancing lesion less than 20 mm in diameter without midline shift on imaging studies in patients lacking signs or symptoms of systemic disease, focal neurologic deficits, or increased intracranial pressure was highly suggestive of neurocysticercosis in a prospective study of 401 patients in southern India.[184] However, the results are less specific in areas with a lower prevalence of cysticercosis. Spontaneous resolution or resolution achieved with antiparasitic drugs is another major criterion.

Serodiagnosis has proved problematic for cysticercosis. ELISAs employing unfractionated antigens, such as cyst fluid, have poor sensitivity and specificity.[176,185] The preferred serodiagnostic test is the enzyme-linked immunotransfer blot employing semipurified parasite glycoproteins.[247] A positive reaction to any one of seven glycoprotein bands is considered positive. ELISAs using recombinant versions of these antigens are being developed.[72] Studies have confirmed a specificity of nearly 100 percent in suspected cases, but the sensitivity is limited in subjects with either a single lesion or only calcified lesions.[89,176,208,258] For this assay, tests of serum are more sensitive than tests of CSF.[258] Assays to detect parasite antigens may prove to be important diagnostic studies.[62,77,79,81,171] Although several different antigen detection tests are in development, none is widely available commercially.

Minor criteria include (1) lesions on neuroimaging studies consistent with neurocysticercosis but less suggestive (e.g., isolated basilar meningitis, hydrocephalus without demonstration of cystic lesions, or filling defects in the spinal subarachnoid space without discrete cysticerci), (2) symptoms suggestive of seizures or hydrocephalus, and (3) cysticercosis outside the nervous system (e.g., cigar-shaped muscle calcifications or subcutaneous nodules).[46] Epidemiologic criteria include residence or prolonged visits to endemic areas and contact with a tapeworm carrier. Since the guidelines were published, publications have reported detection of parasite antigens in CSF, serum, and urine.[41,157,194,255] Currently, no commercial or well-standardized assays are available. Antigen is more frequently detected with viable cysticerci and with a larger parasite burden. They appear to be particularly useful for determining length of therapy in complicated subarachnoid cases. PCR assays have been reported on CSF, but these are also not well standardized.[151]

Numerous other tests may prove useful in excluding other illnesses but are not diagnostic of neurocysticercosis. These tests include blood counts, lumbar puncture for testing of CSF, and stool studies. Lumbar CSF frequently has elevated protein levels and may show hypoglycorrhachia. Cell counts are variable and may demonstrate a predominance of lymphocytes, neutrophils, or eosinophils.

Treatment

For patients with seizures caused by neurocysticercosis, initial management should focus on control of the seizures, which usually can be accomplished with a single antiepileptic drug. Most published studies describe use of phenytoin or carbamazepine. Newer agents (e.g., valproate, lamotrigine, levetiracetam, topiramate, oxcarbazepine, or clobazam) may be more effective, but they are not affordable in endemic areas.[118] Breakthrough seizures usually occur with subtherapeutic antiepileptic drug levels, often from poor adherence to medication therapies.[82] Seizure therapy can be tapered off for many patients after they have a seizure-free period if radiographic resolution of the lesion is seen. However, a substantial risk exists for recurrence of seizures if residual inflamed or calcified lesions are present.[26,82,161,183,251] Antiepileptic drugs should be continued indefinitely if calcifications develop.

Patients with obstructive hydrocephalus usually require surgery.[70,73,160,162,187] For patients with mild or intermittent symptoms (e.g., a cysticercus in the lateral ventricles not associated with midline shift), elective endoscopic removal of the cysticercus is the treatment of choice.[181,187] Cases with altered mental status or impending herniation should undergo emergency CSF diversion by a ventriculostomy or placement of a ventriculoperitoneal shunt. A high rate of shunt failure exists if shunting is not followed by administration of antiparasitic therapy or corticosteroids.[70,119,187,230] Patients with communicating hydrocephalus often require placement of a ventriculoperitoneal shunt.[119] In some patients, cysticerci and associated edema may lead to mass effects. If the symptoms are life-threatening or if the cysticercus is easily approachable (e.g., in the sylvian fissure), surgical decompression of the cysticercus is the preferred approach.

A consensus is emerging among experts about the proper role of antiparasitic drugs and corticosteroids in the management of neurocysticercosis.[70,161] Experts agree that neurocysticercosis represents a spectrum of diseases that differ in optimal management.

Single Enhancing Lesions

The most common presentation of children with neurocysticercosis is seizures and a single enhancing lesion. Seizures generally can be controlled with antiepileptic medications.[118,183,251] Controlled trials of antiparasitic drugs in patients with single enhancing lesions have demonstrated a favorable prognosis with symptomatic therapy. However, the length of time until radiologic resolution is achieved and the duration of time for risk for experiencing seizures appear to be somewhat shorter with antiparasitic drug treatment.[47,218,221,242] By contrast, these treatments do not appear to affect the formation of calcified lesions or development of chronic epilepsy. The role of steroids is better defined; several studies showed clear benefit in reducing seizure activity and faster resolution of the lesion on CT when steroids were used in conjunction with antiepileptic medications.[84,86,127,145,173] Overall, the best evidence points to a small benefit achieved from use of antiparasitic drugs (e.g., albendazole 15 mg/kg/day for 8 days) and a short course of corticosteroids (e.g., prednisone 1 mg/kg/day for 8 to 10 days). A single study suggested

that combinations of praziquantel 75 mg/kg/day and albendazole 15 mg/kg/day may be more effective in children with single enhancing lesions than albendazole alone.[117] The safety of this approach has been confirmed in a pharmacokinetics study in adults.[80]

Multiple Parenchymal Lesions

Patients with seizure activity with multiple cysticerci usually will have one or more lesions in the process of degenerating (e.g., edema or contrast enhancement on imaging studies). However, other cysticerci may be in the viable stage, posing a prolonged risk for having seizures. A placebo-controlled trial from Peru showed a modest reduction in the number of generalized seizures in patients treated with albendazole and corticosteroid,[82] but no decrease occurred in the development of chronic calcifications. A meta-analysis of trials also supported this approach.[47] One recent trial suggested a worse outcome with this treatment, an effect not seen in any other study. Overall, the current expert consensus is that patients with multiple parenchymal cysticerci usually should be treated with a course of an antiparasitic agent (albendazole 15 mg/kg/day in two daily doses for 8 days) and a simultaneous course of corticosteroids.[162] Data from a large clinical trial suggest that the combination of praziquantel and albendazole may be more effective than albendazole alone (H. Garcia, manuscript under review). Even so, symptomatic therapy (e.g., antiepileptic drugs) remains a key to management.

Cysticercal Encephalitis (Numerous Cysticerci with Cerebral Edema)

In this context of diffuse cerebral edema (cysticercal encephalitis), antiparasitic drugs are contraindicated because of their potential to exacerbate host inflammatory responses.[73,186,240] Most cases will resolve spontaneously with anti-inflammatory medications.

Calcified Parenchymal Cysticerci

Parenchymal brain calcifications can be seen in more than 10 percent of residents in some neurocysticercosis endemic areas.[160,184] These parenchymal calcifications are a significant risk factor for having continued seizure activity.[83,183,251] If a patient with a history of seizures has a calcified lesion, that patient should be treated with antiepileptic therapy indefinitely. Recurrent seizures may be due to concomitant mesiotemporal sclerosis.[250] Antiparasitic medications and anti-inflammatory drugs are not indicated. Surgical removal of the calcified focus has been used in some cases of intractable seizures.[257] By contrast, most cases can be managed with a single antiepileptic medication.

Ventricular Neurocysticercosis

Patients with obstructive hydrocephalus usually require surgery. For mild or intermittent symptoms (e.g., a cysticercus in the lateral ventricles not associated with midline shift), elective endoscopic removal of the cysticercus is the treatment of choice.* Cases with altered mental status or impending herniation should undergo emergency CSF diversion by a ventriculostomy or placement of a ventriculoperitoneal shunt. A high rate of shunt failure exists if shunting is not followed by administration of antiparasitic therapy. Cysticerci in the lateral and third ventricles usually can be removed through a rigid endoscope. A flexible endoscope is required to approach the fourth ventricle or basilar cisterns.[105,245,266] Many surgeons, however, prefer a suboccipital craniotomy for removal of cysticerci in the 4th ventricle. Endoscopic foraminotomy and third ventriculostomy often can be used to treat residual hydrocephalus. Antiparasitic medications should not be given before the procedure is performed because they can cause the cysticerci to be friable or to adhere to the ventricular wall. The cysticerci frequently rupture during removal, but this rupture has not been associated with any adverse effects. Endoscopic third ventriculostomy has been used as an alternative to shunting procedures.[104,128,177]

A ventriculoperitoneal shunt may be used to treat hydrocephalus. The rate of shunt failure is high in patients treated only with ventriculoperitoneal shunting. However, shunt failure appears to occur less frequently when patients receive adjunct therapy with corticosteroids and antiparasitic drugs. Although some patients have been treated with only chemotherapy and steroids, a substantial risk exists for development of acute hydrocephalus from cysticerci or accompanying inflammation causing obstruction of the foramina.

Subarachnoid Neurocysticercosis

Basilar subarachnoid cysticercosis is perhaps the most severe form of infection and carries risks for communicating hydrocephalus, vasculitis, and strokes.[70,72,160,162,187] Data on how best to treat this form are limited, but most experts agree that patients should be treated with antiparasitic drugs, corticosteroids, and, in most cases, CSF diversion procedures.[175] Most experts recommend treatment with albendazole, typically 15 mg/kg/day in divided doses for at least 28 days, but cure rarely is achieved with a single course of albendazole. Repeated courses, prolonged therapy, higher doses, switching to praziquantel, and combination of the two drugs have been tried in some cases.[146] In my experience, combination therapy seems to be more effective than albendazole alone. Improved responses with endoscopic debulking of some of the parasites are anecdotal,[94,162] and this approach has not yet been studied systematically.

Inflammation seems to drive much of the pathogenesis, and the residual symptoms may reflect a chronic inflammatory response to cysticercal antigens rather than viable cysticerci. Prednisone up to 60 mg/day or dexamethasone up to 24 mg per day should be used along with the antiparasitic drugs. After 2 to 4 weeks, the dose often can be tapered. In cases that require more prolonged steroid therapy, methotrexate has been used as a steroid-sparing agent.[152]

*References 73, 104, 160, 162, 178, 181, 187, 233.

Giant Subarachnoid Neurocysticercosis

Some cysticerci, particularly in the sylvian fissure or basilar cisterns, may enlarge to more than 5 cm in diameter, causing mass effect either directly or by surrounding edema. If mass effect cannot be reversed quickly by corticosteroids, surgical decompression may be required. In the absence of symptomatic mass effect, however, giant cysticerci can be treated similarly to other subarachnoid cysticerci.[162,175]

Other Forms of Neurocysticercosis

Cysticercosis of the eye, spine, or subcutaneous tissue generally is treated by surgical removal.[70] Anecdotes of medical therapy also exist.

Prognosis

The prognosis of neurocysticercosis is extremely variable, depending on the sort of infection. Patients with single enhancing lesions generally do well and often are seizure free and discontinue therapy within 1 to 2 years. Patients with calcified lesions may require chronic antiepileptic therapy. Patients with numerous subarachnoid cysticerci often require repeated courses of therapy and even repeated surgeries. However, with optimal management of hydrocephalus, cases are rarely fatal.

Prevention

Cysticercosis was eliminated from western Europe by improved sanitation, animal husbandry, and meat inspection.[76,92] For example, porcine cysticercosis can be prevented by not allowing pigs access to human feces.[249] However, confined pigs must be fed, which is not affordable for peasant farmers. Human infection with adult tapeworms also can be prevented by adequate cooking or freezing of infected pork, but meat inspection has not been successful in areas where pigs are slaughtered informally.[237] Mass chemotherapy of endemic populations for carriage of the human tapeworm or porcine cysticercosis has resulted in significant short-term decreases in prevalence,[3,49,92,204] but prevalence rates rapidly return unless mass treatment is continued. Development of an effective vaccine against cysticercosis may provide the best potential tool for eradication of the disease. Promising studies indicate that this will be possible for human and porcine cysticercosis.[66,88,93,112]

COENUROSIS (*TAENIA MULTICEPS*, OTHERS) AND CYSTICERCOSIS CAUSED BY *TAENIA CRASSICEPS*

Several species of *Taenia* have a larval stage called a *coenurus* that consists of a cystic membranous structure measuring up to 6 cm in diameter from which multiple scolices bud internally or externally.[96,107] On the basis of this morphologic appearance, the parasite was given the species name *multiceps*. Currently, the preferred genus name is *Taenia* because of the morphology of the adult worms and the inability to justify a genus designation based solely on the form of larvae. The following species generally are accepted for purposes of discussion. The adult tapeworm of *Taenia multiceps* is found in dogs, and the larval stages occur in herbivores. The larvae often develop in the CNS in sheep. In sheep-raising areas of Europe and Asia, the infection is still endemic in animals. *Taenia serialis* adult worms are found in dogs and other canids, but common intermediate hosts are rabbits, hares, and rodents. The coenurus develops in subcutaneous and intramuscular tissue. *T. serialis* has been reported from the United States, Canada, France, and Africa. *Taenia brauni* is the name given to the tapeworms of dogs, jackals, foxes, and genets found in tropical Africa. The larvae develop in gerbils and other rodents. Humans are a rare accidental host for the larval stages of these worms. Fewer than 100 human infections have been recorded. Most infections are from Africa, with many occurring in children. Giving a species designation based solely on the morphologic features of organisms recovered from human tissue is nearly impossible. The infection is presumed to be acquired by the ingestion of eggs excreted by the definitive hosts, usually dogs. Because of the subcutaneous and subconjunctival locations of cysts in infections in tropical Africa, some researchers have suggested that direct contact of the eggs on skin or the conjunctiva is a mode of transmission. A review of the six human infections in North America has been published.[96,107]

The clinical manifestations of coenurosis are related to the location of the parasite. Involvement of the CNS produces a spectrum of illness that resembles that of cysticercosis (discussed earlier), including meningeal reactions. Larvae have been seen in the subconjunctival and subretinal tissue, the extraocular muscles, the anterior chamber, and the vitreous. Subcutaneous and intramuscular lesions occur most commonly in the abdomen and chest wall. A definitive diagnosis is made by demonstrating the characteristic morphologic features of the larva recovered at surgery. The multiple scolices that bud from the delicate cyst membrane have double rows of hooklets of a typical shape, size, and number. In instances in which no scolices are found, differentiation of a coenurus from a cysticercus of *T. solium* is impossible. The diagnosis of intramuscular coenurosis has been made by examination of fine-needle aspirates.[96,107] Radiographic studies such as CT are useful in cerebral coenurosis but do not differentiate the parasite from other cystic lesions. The metabolic changes of magnetic resonance spectroscopy in an adult with cerebral coenurosis have been reported.[5] Treatment is surgical. Mortality rates in cerebral disease are high. Organisms in other locations, with the exception of subretinal lesions, are removed easily. A combination of praziquantel and a corticosteroid administered to a patient with a subretinal coenurus caused death of the parasite, which resulted in a severe inflammatory reaction, retinal detachment, and permanent loss of vision.[106] Severe reactions were reported in the two additional cases described in this review. Praziquantel should be used with great

caution, if at all, in cases of human coenurosis. Nonetheless, postoperative praziquantel and albendazole have been used without apparent complication.[12,60] Although the exact mode of infection in humans has not been identified, avoidance of close contact with dogs and dog excreta, which are the most likely sources of infection, is prudent.

T. crassiceps cysticerci usually are found in field mice, with the tapeworm found in foxes, other canids, and felines. There have been a few reported human cases with ocular disease or mass lesions in compromised hosts (e.g., patients with acquired immunodeficiency syndrome).* Experimental *T. crassiceps* infection induces a Th2 response that can also modulate immune responses to subsequent pathogenic challenges.[190] Fluid from *T. crassiceps* vesicles has been used to develop ELISA tests, but these tests are not specific for *T. crassiceps* infection and are rather used for seroprevalence studies of neurocysticercosis resulting from *T. solium* infection.[108,174] The diagnosis and management of *T. crassiceps* infection require surgery, but anthelmintic treatment might play a helpful role.[91]

DIPHYLLOBOTHRIUM SPECIES (FISH TAPEWORM)

Diphyllobothriasis can occur in children who ingest raw or undercooked fresh-water fish. The prevalence of infection increases with age in endemic areas. Nonspecific gastrointestinal complaints may occur in infected individuals, and megaloblastic anemia has resulted.[37,115,210,259]

Several species of *Diphyllobothrium* have been reported in humans. *Diphyllobothrium latum* was described first in 1592 from specimens found in Switzerland; it is now estimated to infect approximately 9,000,000 individuals worldwide, with most cases occurring in Europe.[56] *Diphyllobothrium pacificum* is a similar fish tapeworm found infecting humans in Japan and South America, and *Diphyllobothrium nihonkaiense* has been found in Pacific salmon (and, hence, in humans) in Japan and Europe.[37] The *Diphyllobothrium* spp. typically have fish-eating birds, marine mammals, bears, dogs, and foxes as definitive hosts, but children living in endemic areas may be infected when they eat raw or undercooked fish.

The Organism

The scolex of *D. latum* possesses neither discrete suckers nor hooks but has two deep grooves. The worm may be as long as 15 m. The gravid proglottids have a characteristic rosette-shaped central uterus. Eggs measure 55 to 61 μm by 37 to 56 μm and have light brown, operculated shells. The eggs are shed in an unembryonated state from a uterine pore into the fecal stream. The embryos develop within the eggs in fresh water. The ciliated embryos hatch and are ingested by copepods to develop further. After the fish have ingested the infected copepod, the larval stages develop into the plerocercoid stage in the muscles of fish. As the smaller fish are eaten by larger species, the larvae parasitize the muscles of the new host. Eventually, the larvae are found in fish that are sources of food for humans, such as species of pike, perch, turbot, lake trout, and whitefish. The plerocercoid larvae or spargana are white, ribbon-like worms approximately 5 cm in length.

Transmission

Children can be infected by ingesting the plerocercoid forms in raw or undercooked fish muscle that are infectious when ingested by people. Cooking and freezing kill the larvae. The cycle of infection is perpetuated by the discharge of untreated human sewage into fresh-water lakes and streams. Some fish-eating mammals also may serve as definitive hosts for *D. latum* and maintain the cycle of infection in the absence of humans. Because *D. latum* requires intermediate hosts, direct transmission cannot occur, and no techniques of isolation or special precautions are required for infected patients.

Epidemiology

The prevalence of infection increases with age in endemic areas. However, infections have been reported in children younger than 1 year of age.[37] The disease is worldwide in distribution, but higher endemicity is associated with eating fresh-water fish raw, lightly salted, or pickled without cooking. Infection occurs frequently in the Baltic countries and Russia; South America; Scandinavia; Switzerland and the adjacent lake regions of Italy, France, and Germany; the Danube River delta; the lake areas of the northern United States and river deltas of Alaska; and Canada. Pediatric infection by *D. latum* has been identified in school-age children in India, Taiwan, Korea, Argentina, and Hawaii. Salmonid fish (i.e., salmon, trout, whitefish) transmit *D. nihonkaiense* to humans in Japan. Infection of humans with a tapeworm parasite of seals, *D. pacificum*, has been reported from Peru.[115,210]

Pathology and Pathogenesis

Little is known about the direct effects of parasitization, with the exception of megaloblastic anemia.[7] The following factors may be significant: (1) the strains of *D. latum* found in Finland, where anemia occurs, absorb seven times more vitamin B_{12} than do strains from North America, where anemia has not been reported; (2) interference with absorption of vitamin B_{12} occurs in nonanemic carriers as well as in those with anemia, and deficient stores of vitamin B_{12} plus malabsorption of vitamin B_{12} may contribute to the anemic state; (3) dietary intake of vitamin B_{12} may be low in anemic patients, and oral vitamin B_{12} has been shown to cause reticulocytosis in the presence of the worm; (4) worms found in anemic patients take up more of an oral dose of vitamin B_{12} than do worms in asymptomatic carriers, and worms are attached more proximally in the small intestine in anemic patients;

*References 29, 32, 69, 91, 100, 144.

and (5) secretion of intrinsic factor is reduced in anemic patients.

Clinical Manifestations

Most infections are asymptomatic, but patients may notice proglottids or chains of segments in the stool. In Finland, comparison of nonanemic infected patients with uninfected controls revealed an increase in the symptoms of fatigue, weakness, craving for salt, lack of well-being, dizziness, and numbness of the extremities in the infected group.[199] Significant gastrointestinal symptoms occur infrequently. However, an experimental infection with seven larvae produced nausea, severe periumbilical pain, and marked weight loss. Episodes of intestinal obstruction associated with the vomiting of masses of tapeworms have been reported. Eosinophilia is an uncommon finding. Patients with *D. pacificum* reported abdominal pain, vomiting, diarrhea, and flatulence.[141] Megaloblastic anemia caused by *D. latum* infection is extremely rare outside Finland and neighboring endemic areas. Usually, it is seen in patients older than 50 years of age (and may occur in as many as 2 percent of adult tapeworm carriers), but it has been reported in children as young as 9 years.

Diagnosis

Identification of the characteristic eggs (oval, operculated, approximately 60 µm across) or proglottids provides the diagnosis. The parasite produces nearly 1 million eggs per day, and ova usually are detected easily by fecal examination.

Treatment and Prevention

Treatment with praziquantel (5 to 10 mg/kg as a single oral dose) is highly effective. An alternative medical treatment is niclosamide (50 mg/kg as a single oral dose). Tapeworm-related anemia is reversible by treatment of the infection, but the affected child should receive supplementation initially with vitamin B_{12}.

A significant reduction in the transmission of *D. latum* has been accomplished in many areas through the introduction of sewage treatment and targeted drug treatment of human infections. Raw and undercooked fish should not be consumed in areas where a possibility of larval infection exists. Larvae do not survive in fish that is either cooked for 5 minutes or more at temperatures of at least 55°C or frozen at temperatures of at least –10°C for 8 to 72 hours.[56]

DIPYLIDIUM CANINUM (DOG TAPEWORM)

Dipylidium caninum, the common tapeworm of dogs and cats, also infects infants and young children.[37,259] Transmission occurs through the accidental ingestion of infected fleas (*Ctenocephalides* spp.) or body lice (*Trichodectes* spp.). Although it usually is asymptomatic, infection may be associated with decreased appetite, abdominal discomfort, or, perhaps, diarrhea.

The Organism

D. caninum adult worms have a scolex with four cup-shaped suckers and a rostellum that bears one to seven rows of small hooks. The worm ranges from 10 to 50 cm in length. The gravid proglottids resemble cucumber seeds in size and shape. The proglottids have two pairs of sex organs, and a genital pore opens on each lateral margin. The eggs measure 35 to 65 µm in diameter and appear in packets of 5 to 30 enclosed in a membrane. The gravid proglottids are excreted in feces or migrate actively from the anus. The eggs are liberated as the proglottid disintegrates. Several species of flea serve as intermediate hosts. The larval flea ingests the egg of *D. caninum*. Development of the tapeworm's larval stages takes place as the flea metamorphoses into an adult. When the flea is ingested by the definitive host, the adult worm develops in the small intestine.

Transmission and Epidemiology

Humans acquire the infection by the accidental ingestion of infected fleas. Dogs may transfer infective larvae to humans by licking children after crushing fleas orally. Because of the motility of the proglottids, eggs may be disseminated widely in the environment of animal hosts. Fleas are so ubiquitous that transmission to the intermediate host is accomplished readily.

Infection of dogs and cats is a common occurrence worldwide. *D. caninum* also has been found in a variety of wild canines and felids. Reports of dipylidiasis in humans in the United States, however, are uncommon.[27,154]

Clinical Manifestations, Diagnosis, Prognosis, and Treatment

Although the incubation period in humans is unknown, infection has been seen in infants aged 5 weeks. Frequently, the only evidence of infection is the finding of proglottids in stool or in an infant's diapers. Varying degrees of abdominal pain, diarrhea, irritability, and even pruritus have been recorded in symptomatic children.

The characteristic proglottids must be differentiated from other parasites. A frequent error is to assume, from the parents' description, that the small, motile proglottids that migrate from the anus are pinworms. Proglottids also may be mistaken for fly larvae. Examination findings of stool specimens may be spuriously negative because proglottids tend to migrate from the fecal mass and disintegrate on the walls of the specimen container. Treatment with praziquantel 5 to 10 mg/kg as a single oral dose is effective. An alternative treatment is niclosamide 50 mg/kg as a single oral dose.

Infected dogs and cats also should be treated. Flea control requires the use of appropriate insecticides on pets. In addition, particular attention must be given to carpets and areas where pets sleep because these are the sites of development of the larval fleas.

HYMENOLEPIS NANA (DWARF TAPEWORM)

Infection with *Hymenolepis nana*, the dwarf tapeworm, occurs worldwide and probably is maintained by direct fecal-oral transmission from person to person.[37,259] Insects may serve as intermediate hosts. Infection may be asymptomatic, but gastrointestinal, neurologic, and allergic symptoms have been reported.

The Organism

Adult worms of *H. nana* measure 1 to 5 cm in length and are less than 1 mm in maximal width. The tiny scolex has four cup-shaped suckers and a rostellum with a circle of 20 to 30 small hooks. Gravid proglottids disintegrate within the intestine, and eggs are found in the feces. The oval eggs measure 30 to 50 μm in diameter and contain a six-hooked embryo within two envelopes. The space between the two envelopes contains filaments that extend from two small polar protrusions on the inner envelope. Larval stages develop in insect intermediate hosts after they have ingested the eggs. However, if the definitive host ingests eggs, larval stages develop in the intestinal villi in 4 to 5 days and then break into the lumen and develop into adult worms. Ova appear in feces 2 to 4 weeks after infection occurs. A morphologically identical organism found in rodents may be a separate species. The rodent strains are alternatively called *Hymenolepis fraterna* or *H. nana* var. *fraterna*.[37,143] The rodent strain occasionally infects humans.

Transmission

Human infection is acquired most commonly by the ingestion of eggs from the feces of infected persons. Humans serve as both intermediate and definitive hosts in this direct cycle. Poor hygienic habits, overcrowding, lack of running water, and any other factor that fosters fecal-oral transmission enhance transmission through this route. The rodent strains of *H. nana* are infectious for humans, and food contaminated by rodent feces is a possible source of infection. Eggs may be produced for periods longer than 1 year, but the possibility of recurrent autoinfection obscures determination of the duration of the initial infection. Internal autoinfection may occur when ova from gravid proglottids are exposed to appropriate conditions within the intestinal lumen. Hatching occurs, and the embryos penetrate the mucosa, undergo larval development, and eventually emerge as adult worms.

Epidemiology

H. nana is a common parasite of rats and mice worldwide, and 50 to 75 million people are thought to be infected.[37,259] The distribution of infection in humans is worldwide, with an increased prevalence in some urban areas. Stool surveys from endemic areas commonly show prevalence rates of 5 to 25 percent, which may approach 50 percent in children aged 4 to 10 years.[40]

Pathology and Pathogenesis

Little is known of the pathogenesis and pathology of *H. nana* infection in humans. The larval stage of *H. nana* is a cystlike structure called a *cysticercoid* that is approximately 250 μm in diameter. Local reactions consisting of mucosal inflammation or atrophy may occur at the site of attachment of the adult worms in the small intestine. Rare cases of disseminated infection in children with depressed cellular immunity have been reported.[140]

Clinical Manifestations

A wide variety of symptoms have been ascribed to *H. nana* infection, but few well-controlled clinical studies have been presented. Heavy burdens of worms have been associated with abdominal pain, diarrhea or loose stools, malnutrition, retardation of growth, and lethargy, whereas children with low burdens did not have significant symptoms.[30,31,223]

Diagnosis

Detection of the characteristic eggs in fecal material by examination of direct saline wet mounts or by concentration techniques usually is not difficult. However, a single examination is not always adequate to rule out infection.

Treatment and Prognosis

Praziquantel 25 mg/kg as a single oral dose is effective in treating *H. nana* infection. Nitazoxanide 100 mg by mouth twice daily for 3 days for children 1 to 3 years of age, 200 mg by mouth twice daily for 3 days for children 4 to 11 years of age, and 500 mg by mouth twice daily for 3 days for older children is a reasonable alternative therapy; efficacy is approximately 75 to 82 percent.[30,170] Family members should be examined and treated if they are infected. Infection with *H. nana* rarely is severe and responds well to appropriate treatment.

Prevention

Transmission of *H. nana* infection largely could be eliminated if proper methods of personal hygiene and disposal of human waste could be invoked throughout the world. Infected foodhandlers always should be treated and monitored to ensure that treatment has been successful. Stored food should be protected from rodents and insects.

HYMENOLEPIS DIMINUTA (RAT TAPEWORM)

Hymenolepis diminuta is a rat tapeworm that only rarely presents as a human infection. Adult worms are 20 to 90 cm long and the eggs are round.[37,259] Children become infected after ingesting larva-infected insects. Infection often is asymptomatic, but abdominal discomfort and pruritus have been reported. Treatment is with praziquantel 25 mg/kg in a single oral dose or niclosamide.

SPARGANOSIS (INTERMEDIATE-STAGE *SPIROMETRA* SPECIES INFECTION)

Sparganosis is a zoonotic infection seen most frequently in eastern Asia.[96,259] It occurs when humans are infected with a metacestode larval stage of *Spirometra* spp. The condition is also referred to as "plerocercoidosis" and is often caused by *Spirometra erinaceieuropaei* in Asia and *Spirometra mansonoides* in the Americas.[6]

The Organism

Evidence indicates that the amorphous, thin, ribbon-like *Spargana* organisms recovered from human infections belong to the genus *Spirometra*.[96,259] The adult tapeworms are found in dogs, cats, raccoons, and a variety of wild carnivores. Eggs passed in the feces of these definitive hosts hatch in fresh water. The embryo that emerges from the egg is ingested by a copepod, where it undergoes larval development as a procercoid. When a second intermediate host ingests the infected copepod, the larva develops into a sparganum (plerocercoid). The range of second intermediate hosts includes amphibians, reptiles, birds, and mammals. When the second intermediate host is eaten by the definitive host, the sparganum attaches to the intestinal mucosa and develops into the adult tapeworm. A rare form of sparganosis that buds, branches, and multiplies asexually to massive numbers in humans is called *Sparganum proliferum*.[158]

Transmission

In parts of Asia, application of poultices of amphibian or reptile flesh to wounds or sores is a common practice, and children can be infected when the *Spargana* organisms migrate from the poultice into human tissues. Human sparganosis in the United States often is associated with drinking well water or untreated surface water that could contain the minute copepods containing the procercoid form. Transmission by ingestion of the raw or inadequately cooked flesh of second intermediate hosts has been demonstrated experimentally in humans. Animal sources such as snakes, frogs, chickens, and pigs have been incriminated in human infection. Asymptomatic cats, especially those living outdoors, are infected in some areas.[99,111,200]

Epidemiology

Human infection is not uncommon in Thailand.[6] It is also widely reported from China, Korea, Japan, India, Indonesia, the Philippines, Australia, Africa, Italy, South America, and the former Soviet Union.[96,136,259,260] With changes in lifestyle and environmental control, the rate of sparganum seropositivity among patients suspected of having parasitic disease in South Korea dropped from 2.6 percent in 1993 to 1.6 percent in 2006.[131] However, the infection still seems to be a bit less uncommon in North Korea.[216] In the United States, almost all reports have come from the southern or southeastern states and from Puerto Rico or were reported in persons who had been in these areas, but one infected child was reported from southern California.[35]

Pathology, Pathogenesis, and Clinical Manifestations

Ocular sparganosis, usually acquired by contact, may involve conjunctival, retro-orbital, or palpebral tissues and cause conjunctivitis, periorbital and palpebral edema, exophthalmos, chemosis, and corneal ulceration.[96,259,260] Subcutaneous sparganosis is the most common form of the infection, with the trunk frequently being involved. The lesion usually is nodular. Tenderness and inflammation may be absent, intermittent, or constant. Some lesions are migratory. Eosinophils may or may not be present. Some infections have had an associated peripheral eosinophilia, but it is not a constant finding. Spargana have been identified in a wide range of other tissues. Sparganosis of the CNS may be associated with a variety of neurologic manifestations.[96,126,226,259,260] Brain imaging of patients with cerebral sparganosis shows edema and degeneration of cerebral white matter commonly with a "tunnel sign" of hypodensity and ring enhancement.[226] Sequential MRI imaging has revealed migration of larva between various regions of the brain in some children.[14,137] The disease caused by *Sparganum proliferum* consists of progressive replacement of host tissues by the multiplying organisms.

Diagnosis

The diagnosis may be suspected in persons with typical subcutaneous lesions and a suggestive epidemiologic background. Usually, however, the diagnosis is made during surgical removal of a painful or cosmetically disturbing lump without anticipation of the parasitic etiology. *Spargana* organisms vary considerably in width and length. They usually are several centimeters in length, whitish, and opaque, and they may have the grooved indentations on the anterior end that are precursors of the bothria, or suckers of the scolex, of the adult worm. Small portions of *Spargana* are difficult to distinguish grossly or microscopically from cysticerci and other less common larval cestodes. Neuroimaging may yield characteristic findings in cerebral sparganosis.[126,226] Performing an ELISA or serum and CSF antibody appears to be useful in endemic areas, but this test is not generally available.[259]

Treatment and Prevention

Surgical removal is the only known form of therapy. Stereotactic aspiration and microsurgery have been effective, but care to remove all larval material is essential.[51] Praziquantel has been used in some cases, but no convincing evidence of clinical activity exists. Filtration of water prevents the ingestion of copepods from wells or ponds. Proper cooking of meat eliminates second intermediate hosts as sources of infection. Educational effort should be made to warn of the dangers of applying raw flesh poultices in areas where it is a cultural practice.

ECHINOCOCCUS GRANULOSUS AND RELATED SPECIES (CYSTIC HYDATID DISEASE)

Humans may be infected with the larval stages of parasites of the genus *Echinococcus*.* Humans acquire the infection by the ingestion of ova from the feces of carnivorous definitive hosts. The disease in humans and intermediate hosts is hydatid disease and is characterized further according to the morphologic features of the larval stages: cystic echinococcosis caused by *Echinococcus granulosus* and related organisms, alveolar echinococcosis caused by *Echinococcus multilocularis*, and polycystic echinococcosis caused by *Echinococcus vogeli* or *Echinococcus oligarthrus*. Most cases in children present with cystic hydatid disease, which is the focus of this section of the chapter.†

The Organisms

Cystic hydatid disease is caused by *E. granulosus* and related species. On the basis of morphologic features, all cases initially were considered to belong to a single species. However, genetic studies have demonstrated 10 separate genotypes that infect different intermediate hosts.[58,113,206,238] Significantly different strains are found in sheep, Tasmanian sheep, cattle, pigs, horses, camels, and cervids (i.e., deer, reindeer, moose, elk). Most human infections are caused by the sheep strain. However, Tasmanian sheep, cattle, camel, and cervid strains also can cause human infection. The life cycles of the species of *Echinococcus* are similar, but the geographic distributions, types of hosts, and morphologic features of the parasites differ significantly. Adult tapeworms of the sheep strain are found in dogs. The cervid strain involves primarily wolves, but dogs also may be infected. The adult tapeworm is only 3 to 8 mm long and has two to five segments. Dogs often are hosts to thousands of adult worms. When sheep or humans ingest eggs from the feces of infected dogs, the embryos hatch in the intestine and burrow through the intestinal wall to gain access to the portal circulation. The embryos that survive are able to develop in many tissues, but they do so most commonly in the liver or lungs, where they become the cystic larval structures called *hydatid cysts*. A hydatid cyst is composed of an outer laminated, acellular membrane that is lined by a thin, cellular germinal membrane. Spherical structures called *brood capsules* grow from the germinal membrane. Protoscolices develop within the brood capsules. Each protoscolex has suckers and hooks and the potential to become the scolex of an adult worm if it is eaten by a dog. Compression and reaction from growth of the cyst produce a "pericyst" of compact, collagen-rich host tissue around its exterior. In older cysts, so-called daughter cysts may develop within the primary cyst cavity.

*References 16, 17, 38, 39, 58, 59, 113, 206.
†References 16, 38, 39, 58, 59, 113, 206.

Transmission

Humans acquire cystic hydatid disease by ingestion of ova shed by the definite host, typically dogs.[39,58,150,156,201,206] Close contact with dogs can result in infection because tapeworm eggs can be found on the dog's perianal hair, muzzle, and paws. Contaminated food, drink, or fomites (e.g., flies and other insects) may disseminate the eggs from dogs' feces. However, most cases occur in pastoral families and are associated with close contact with infected dogs.

Epidemiology

The sheep strain of *E. granulosus* is found worldwide in most areas where sheep are raised.* Studies of the global burden of disease and economic impact of cystic hydatid disease suggest that the impact is significantly underestimated in contrast to other illnesses.[21] The disease is endemic in the sheep-raising areas of South America, the Middle East, the Mediterranean basin, China, and the former Soviet Union.† One of the highest morbidity rates is seen in rural Africans in Kenya and Uganda, where people live in close association with their dogs. The custom of feeding sheep viscera to sheepdogs maintains foci of infection. In the United States, Basques in central California, Mormon ranchers in Utah, and Native Americans in Arizona and New Mexico have been infected. The cervid strain of *E. granulosus* is found in northern parts of the Western Hemisphere. In Alaska and Canada, human infection usually is limited to Eskimos and Native Americans who have working dogs that are fed moose and reindeer viscera.[239] The strain found in this region often is manifested as giant pulmonary cysts.

Pathology and Pathogenesis

In cystic hydatid disease, the pathologic process is related to compression or displacement of the host's tissue.[58,172,206] Cyst growth is variable but probably averages approximately 1 cm in diameter per year. Rates of up to 4 to 5 cm per year have been reported, but growth may be more rapid in the lung. The cyst may exceed 35 cm in diameter in the abdominal cavity. When rupture or leakage of a cyst occurs, an allergic reaction caused by the antigenic cyst contents may develop. Cysts may calcify after many years, which usually signifies death of the parasite. Hydatid cysts may form foci for secondary bacterial infection.

Clinical Manifestations

Most children with *E. granulosus* infection have a single unilocular cyst, but multiple cysts are seen in 15 to 30 percent of patients, usually in a single organ system.[58,172,206] The most common site of the cysts is in the liver. In clinical series, approximately one in five children with a pulmonary cyst also has a concurrent liver cyst, but the

*References 16, 39, 58, 113, 150, 156, 206.
†References 19, 39, 58, 113, 150, 156, 201, 206.

proportion outside the liver is lower in population-based screening.[49] Approximately 10 percent of cysts are found in sites other than the liver or lung, including the spleen, kidney, peritoneum, genitourinary tract, bone, muscles, heart, eye, and brain. The cervid strain of *E. granulosus* found in Canada and Alaska characteristically produces pulmonary cysts.[58,172,206] CNS hydatid disease occurs much more commonly in children than in adults.* Bone cysts, which may be seen in preschool children, occur most frequently in vertebral and long bones.[172,206] Unlike cysts in other sites, bone cysts characteristically are multilocular and contain little fluid. Eye, bone, and brain cysts typically are small when they are discovered, whereas cysts in other sites may exceed 35 cm in diameter before being detected. Cysts grow approximately 1 to 3 cm in diameter each year, but growth may be more rapid with pulmonary cysts. Complications usually occur only if cysts become large and include secondary bacterial infection of hydatid cysts and leakage or rupture with resultant hypotension, urticaria, and eosinophilia. Rupture may occur spontaneously or secondary to trauma or surgery, but it generally is considered to be an uncommon complication of hydatid disease in children.

The wide spectrum of symptoms in cystic hydatid disease depends on the number, size, and location of the cysts.[58,172,206] Slowly growing cysts in liver or lung often are asymptomatic for years. Symptomatic intrahepatic cysts cause constant or intermittent right upper quadrant or epigastric pain, enlargement of the liver, or nausea and vomiting. Unruptured cysts rarely cause fever. Rupture of a cyst may be precipitated by a traumatic event and may cause a range of symptoms, including fever, abdominal pain, hypotension, and allergic manifestations, including eosinophilia, urticaria, and anaphylaxis. Rupture into the biliary tract may cause cholangitis with fever and right upper quadrant pain. Some children with hydatid disease also have retarded growth patterns.[149]

Intact pulmonary cysts typically do not cause symptoms.[58,172,206,215,244] Rupture or leakage, however, may cause cough, chest pain, dyspnea, hemoptysis, and a salty taste. Fever may be present, but it is often a marker for secondary bacterial infection. As many as a third of pulmonary cysts rupture into the pleural space or into a bronchus. In the latter case, the patient may describe coughing up portions of the membranes, which may resemble grape skins, or noting a characteristic salty taste. Bone cysts are seen in patients with bone pain or pathologic fracture. Vertebral hydatid disease causes signs and symptoms of spinal cord and radicular compression; severe pain on palpation of the affected portion of the spine is characteristic. Of intracranial cysts, 50 to 75 percent are seen in children.[34,90,123,248] Increased intracranial pressure with headache, vomiting, and focal neurologic symptoms are common findings. Seizures also may occur.

Diagnosis

The diagnosis of cystic echinococcosis usually is suspected on the basis of clinical or radiologic findings plus a history of residence in an endemic area.[16-18] Physical examination rarely is definitive. Only half of patients with hepatic cysts have abnormal liver enzyme results. Eosinophilia typically is low grade or absent. The initial diagnosis of cystic hydatid disease often is based on imaging findings. An unruptured pulmonary hydatid cyst has a sharply demarcated, round or oval smooth border. In the lung, it has a homogeneous cannonball appearance and sometimes is surrounded by a layer of atelectatic lung.[58,172,206] After the cyst has ruptured into a bronchus, a crescent-shaped air layer may be seen that is virtually diagnostic. In addition to the arc of air between the parasite and the host cyst wall, air in the cyst lumen also may be present. The membrane of a collapsed cyst floating on the surface of the fluid in a ruptured pulmonary cyst has a characteristic "water lily" appearance.

Cysts in the liver usually are visualized easily and measured with ultrasonography, CT, or MRI. Ultrasound techniques are useful for defining most cysts within the abdomen and can differentiate fluid-filled cysts from solid tumors. Because ultrasonography is portable and relatively inexpensive, it has been the main technique used in epidemiologic studies and clinical cases in developing countries. A World Health Organization staging system has been developed to define management (Fig. 226-4).[8,196,256] Stage CL cysts are unilocular collections without a discrete wall and with uniform anechoic contents. This appearance is not specific for *Echinococcus*. Stage CE1 cysts have a dense wall and may have internal echoes. This so-called hydatid sand is caused by protoscolices within the cyst. CE2 cysts have internal septa or daughter cysts, forming honeycomb patterns, that are highly characteristic of hydatid cysts. CE3 cysts demonstrate detachment of the cyst wall or early collapse. CE4 cysts demonstrate inhomogeneous material instead of a cyst cavity. CE5 cysts demonstrate a thick rim of calcification. Radiographically apparent cyst wall calcification occurs only in liver or spleen cysts and generally takes more than 5 to 10 years to develop. Bone cysts typically produce radiolucencies without periosteal reaction. MRI offers little advantage over CT for the imaging of cysts except in the CNS and for demonstration of biliary fistulas.[102]

Fine-needle aspiration of cysts for establishment of the diagnosis can be dangerous if it is not performed carefully because of the risk for spillage of hydatid fluid, which can induce anaphylactic shock and possibly secondary cyst development. However, the percutaneous route has been used for both diagnosis and treatment, with few untoward events (see later discussion). The fluid obtained should be examined for evidence of protoscolices, hooks, or antigen.

Serologic tests can be useful in confirmation of the diagnosis.[58,172,206] Antibody tests using crude antigen of either *E. granulosus* or *E. multilocularis* tested by ELISA, indirect hemagglutination, and fluorescent antibody assays are positive in 50 to 90 percent of cases. False-negative results are more common in patients with pulmonary, brain, and splenic cysts. Because the tests available may cross-react with cysticercosis or other parasitic infections, positive results should be confirmed by a more specific test, either an immunoblot assay or a gel diffusion assay.

Treatment and Prognosis

The treatment of cystic hydatid disease is in evolution.[17,18] Surgery was the traditional treatment of choice for nearly all cases of cystic hydatid disease, but that approach has given way gradually to a range of approaches, including surgery, antiparasitic chemotherapy, percutaneous drainage termed PAIR (*p*ercutaneous *a*spiration, *i*ntroduction of scolicide, and *r*easpiration), and "watch and wait."[18,58,206] Currently, expert opinion suggests that treatment should vary on the basis of the location of the cyst or cysts, the nature and size of the cysts, the condition of the patient, and the available expertise with surgery required by only a minority of cases. For example, in a prospective study, only 10 percent of children with hepatic cysts detected in a population-based ultrasound survey required surgery during the subsequent 5 years.[49,129]

The benzimidazoles albendazole and mebendazole have been used for chemotherapy.* Approximately a third of hepatic cysts will resolve in response to benzimidazoles, and 30 to 50 percent improve. Many of the residual lesions considered treatment failures were shown subsequently to be nonviable. The response to chemotherapy is better with smaller lesions. It is now thought to be the treatment of choice for small (<5 cm) CL, CE1, and perhaps CE3 lesions.[18,58,206] Chemotherapy also has proved to be successful for treatment of small pulmonary cysts.[53] However, a high failure rate exists with chemotherapy alone for larger lesions in either the liver or the lung.[18] Albendazole is thought to be more effective than mebendazole. Albendazole typically is dosed at 10 to 15 mg/kg/day in two daily doses continued for 3 to 6 months. Side effects may include neutropenia, elevated liver enzymes, and alopecia. Prospective studies of surgically removed specimens show that protoscolices can remain viable for as long as 3 months, which is the minimum duration of chemotherapy.[13,63] Treatment failures have been successfully managed by further chemotherapy, PAIR, or surgery. In some cases, PAIR may demonstrate that protoscolices no longer are viable, even with persistent lesions. Because chemotherapy can be associated with relapses or treatment failure, children should receive follow-up imaging studies for years after receiving chemotherapy. Chemotherapy also is an important adjunct to surgical therapy.

The PAIR technique offers a less invasive option than the traditional surgical approaches.* Results have been similar to those with surgery, but with fewer perioperative complications. PAIR is thought to be the treatment of choice for uncomplicated CL and CE1 lesions larger than 5 cm and CE3 lesions. CE2 lesions can be treated with a modification of PAIR that employs a larger bore catheter and drainage.[19,209] Although the data comparing different treatments are limited, PAIR was associated with similar efficacy and less morbidity than surgery in one randomized trial. PAIR should be performed after initiation of albendazole chemotherapy for at least 4 hours but preferably for several days. In a controlled trial, PAIR plus chemotherapy was superior to either chemotherapy or PAIR alone.[124,163] Aspiration generally should go through solid tissue (e.g., liver) rather than directly into the cyst (to limit spillage). The cyst fluid should be examined for protoscolices or hooks (to confirm the diagnosis). Before scolicidal agents are injected, the cyst fluid should be checked for bile staining (by dipstick or, preferably, by injection of contrast medium) because these agents can cause sclerosing cholangitis if they are injected into the biliary tract. Alcohol and hypertonic saline have been used as scolicidal agents in this procedure. Contraindications to PAIR include communication with the biliary tract, inaccessibility, superficial cysts, and cysts that are free in the abdomen, heart, brain, or spine. If the cyst is found after puncture to communicate with the biliary tract, contrast media can be used to further define

*References 58, 63, 68, 122, 129, 206, 231, 243.

*References 18, 19, 64, 125, 163, 206, 225, 261, 262

the communication. Contrast material also is mildly scolicidal.

Surgery has been the traditional approach to therapy for hydatid disease and remains the treatment of choice for complicated infections and some CE3 lesions.[18,58,172,206] The goal of surgery is to remove the entire cyst without spilling its contents. Rupture of the cyst contents at the time of surgery carries a risk for causing disseminated echinococcosis and a small risk for anaphylaxis occurring at the time of operation. Surgical approaches have included pericystectomy (removal of the entire cyst and a rim of surrounding tissues), resection of the involved organ, simple drainage, omentoplasty, and capitonnage. In general, the more radical procedures have been associated with fewer relapses, but at the cost of more perioperative complications. However, laparoscopic approaches have been reported recently to be associated with a high success rate and less morbidity.[23,57,142,262] Chemotherapy with albendazole with or without praziquantel is performed routinely.[10,63,206] With administration of chemotherapy, pressure within the cyst may be reduced, and removal of cyst membranes and contents will be facilitated. In addition, treatment decreases the likelihood of development of secondary cysts. With albendazole alone, cysts remain viable for as long as 3 months.[13] The preoperative administration of praziquantel combined with a benzimidazole has been suggested because of the scolicidal properties of praziquantel.[10] The practice of injecting the cyst with scolicidal drugs before removing it is associated with complications and is not thought to be necessary in the setting of preoperative and postoperative chemotherapy.[206]

Pulmonary cysts have been treated successfully surgically, medically, and with PAIR.* No controlled trials of these different strategies have been performed. However, retrospective series suggest that smaller cysts often respond to antiparasitic chemotherapy.[53] Larger cysts may be treated with surgery. The cervid strains of *E. granulosus* from Alaska and Canada do not produce anaphylaxis on rupture, and pulmonary cysts spontaneously resolve after evacuating into bronchi. If the cyst wall remains in place after the patient has undergone chemotherapy or PAIR, residual parasite material can serve as a nidus for bacterial superinfections.[1] Thus, many experts recommend against PAIR for pulmonary disease.[18]

The prognosis of hydatid disease varies widely from self-limited asymptomatic infection to fatal infection associated with rupture of the cyst. All of the modes of therapy are associated with relapse during the first few years of treatment. Thus, careful follow-up is essential. With appropriate therapy, however, few cases are fatal.

Prevention

Control programs for cystic hydatid disease have met with variable success.[38,39,206] *E. granulosus* was eliminated from Iceland by banning home slaughter of sheep. Banning of home slaughter, education, arecoline purging of dogs, and treatment of infected dogs with praziquantel led to eradication in New Zealand and Tasmania. However, these eradication programs required significant resources and have been less successful elsewhere. A recombinant vaccine has proved to be highly effective in field studies but awaits implementation.[39] Other tools in developmental stages include coproantigen tests to detect infected dogs and improved therapy for ovine infection.

OTHER *ECHINOCOCCUS* SPECIES

Echinococcus multilocularis is the cause of alveolar hydatid disease.[58,113,121,172,206] Humans are an incidental host in a life cycle that typically involves foxes as definitive hosts (but also wolves and occasionally domestic dogs) and rodents as intermediate hosts. The larval parasite does not form a large cystic structure but grows by progressive external budding. The laminated membrane and host pericyst are thin. The larval mass slowly enlarges and replaces liver tissue much as a malignant neoplasm does. *E. multilocularis* is endemic in arctic and alpine areas, including western China, central Europe, and scattered foci in North America. In recent years, disease is emerging in much of central Europe. The larvae may invade contiguous structures and rarely metastasize. Human infection almost invariably involves the liver, but it may spread to adjacent tissues or metastasize to the brain. Because the larval mass grows slowly, with a typical latent period of 5 to 15 years before clinical presentation, clinical disease is a rare finding in children. Diagnosis involves imaging studies with serologic confirmation. Management requires surgical resection along with prolonged chemotherapy. Comprehensive reviews of epidemiology, clinical manifestations, diagnosis, and management are available.*

E. vogeli is a parasite of bush dogs and feral dogs in South America.[206] The intermediate hosts are rodents (i.e., pacas, agoutis, spiny rats). When humans are infected, the germinal membrane grows externally to form additional cysts, and septa develop within the original cyst. This manifestation is the "polycystic" variety of hydatid disease. A rare polycystic hydatid disease in humans has been attributed to *E. oligarthrus*, a fourth species that is found as adult tapeworms in wild felids such as pumas and jaguars. The intermediate hosts are the same as those for *E. vogeli*. Most infections occur in Central and South America. Polycystic hydatid disease is limited to South and Central America, where fewer than 100 human infections have been reported. Initial management should include administration of albendazole.

SUBSECTION 4 *TREMATODES*

CHAPTER 227

Foodborne Trematodes

Miguel M. Cabada • Philip R. Fischer • A. Clinton White, Jr.

An estimated 56 million people are infected with foodborne trematodes, referred to as flukes. Almost 8 million have heavy infections.[33] Approximately 10 percent of the world's population is at risk for acquiring a trematode infection.

Flukes are flatworms (members of the phylum Platyhelminthes and of the subphylum Trematoda) (Figs. 227-1, 227-2, and 227-3).[48,66,88] The adult forms of foodborne trematodes are flat and leaf-shaped, with an oral and ventral sucker and a bifurcated, blind-ended gastrointestinal tract. Foodborne trematodes are hermaphroditic, producing operculated eggs that typically are passed in host feces. Eggs possess an operculum at one end, the opening through which a ciliated larva will hatch. Freshwater snails are intermediate hosts for all trematodes and are infected by either direct penetration by the ciliated larva or by ingestion of the unhatched egg. Complex larval development and multiplication occur within the snail host, with large numbers of larvae called *cercariae* ultimately produced. In most trematode life cycles, the cercariae emerge from the snails and swim about until they are ingested by or attach to the second intermediate host, which may be fish, crustaceans, mollusks, or aquatic vegetation. After attachment occurs, the larvae develop into metacercariae within protective cyst walls. Humans are typically infected by ingestion of the metacercariae. In Southeast Asia and the western Pacific region, foodborne trematodiasis has become an emerging public health problem, associated with the growth of aquaculture.[34,50] Many of the medically important flukes have a wide range of definitive hosts. Diagnosis of fluke infections typically is accomplished by examination of fecal specimens (or sputum in the case of *Paragonimus* spp.) for characteristic ova. Immunodiagnostic tests are available to aid in establishing the diagnosis of some flukes and are becoming the preferred method of diagnosis for certain species. Common liver, intestinal, and lung flukes are reviewed in this chapter.

LIVER FLUKES

CLONORCHIASIS AND OPISTHORCHIASIS

Three similar trematodes of the genus *Opisthorchis* infect the bile ducts of humans.[34,35,51,66] Although the name *Opisthorchis sinensis* is proper parasitologically, this organism is commonly referred to as *Clonorchis sinensis*, and the name of the infection, clonorchiasis, is well entrenched in the clinical literature. *Opisthorchis viverrini* and *Opisthorchis felineus* have similar life cycles and produce similar lesions and illnesses in humans.

The Organisms

The adult flukes measure 4 to 25 mm in length and 2 to 5 mm in breadth and have an anterior oral sucker. The life cycle involves primarily humans, but dogs and cats also act as definitive hosts. Fresh water snails and fish participate as first and second intermediate hosts. In the definitive hosts, parasites are found mainly in the intrahepatic biliary ducts and occasionally in the extrahepatic and pancreatic ducts. *Opisthorchis* spp. and *Clonorchis* spp. produce small operculated eggs (30×16 μm), which are nearly identical morphologically. The ova are shed into bile and excreted in feces. The snail host ingests the embryonated eggs, and after a complex cycle of asexual reproduction, free-swimming cercariae emerge 6 to 8 weeks later. The cercariae encyst under the scales or in the muscle of fresh-water fish as metacercariae. Humans and other definitive hosts are infected by ingestion of raw, inadequately cooked, or pickled fish infected with metacercariae. The larvae excyst in the intestine and migrate to the intrahepatic bile ducts through the ampulla of Vater. Juvenile flukes travel along the biliary tree against bile flow and attach to the bile duct epithelium with their suckers. Adult worms begin producing eggs approximately 4 weeks after ingestion and can survive for as long as 30 years.

Transmission and Epidemiology

Transmission is through the ingestion of raw or inadequately cooked fresh-water fish infected with metacercariae. Cats, dogs, civet cats, and other fish-eating mammals serve as definitive hosts in nature. The expansion of aquaculture in China and other Asian countries and poor sanitation practices allow the contact of human feces with snails in ponds where fish are raised. This situation increases the risk for parasite transmission and hinders control efforts.[31,38]

An estimated 600 million people are at risk for *O. sinensis* infection, 67 million for *O. viverrini*, and 12 million for *O. felineus*.[33] *O. sinensis* is endemic in China, Japan, Korea, Taiwan, and Vietnam. Some of the highest infection rates are reported in endemic areas of China (16%) and Vietnam (26%).[41] *O. viverrini* is endemic to Thailand, Lao People's Democratic Republic, Vietnam, and Cambodia. In northern Thailand, infection rates may reach 60 percent and it is estimated that 7 million residents are infected in that area.[84] *O. felineus* is endemic in central Siberia and in eastern and southeastern Europe. Sporadic infections with *O. felineus* have been reported from several Asian countries.

Eating habits and snail presence are the major determinants for the geographic distribution of the infection. The three species of *Opistochis* follow similar patterns of infection in most areas. The lowest prevalence and intensity of

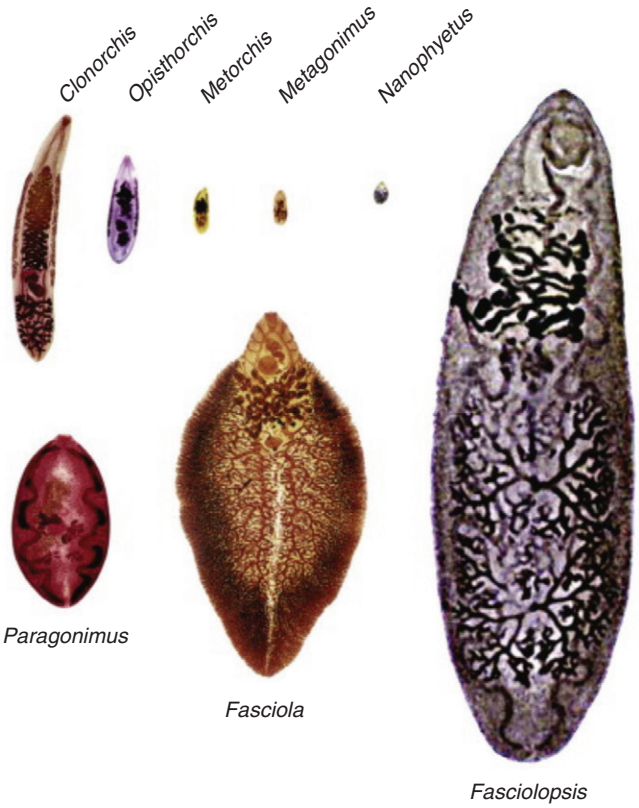

FIGURE 227-3 ■ Adult worms of foodborne trematodes. This is a 3-fold magnification of selected adult flukes illustrating their relative sizes. Actual lengths: *Nanophyetes salmincola* 0.8-2.5 mm, *Opisthorchis viverrini* 5-10 mm, *Paragoniums westermani* 7-16 mm, *Fasciola* 20-30 mm, and *Fasciolopsis* 20-75 mm. (See companion Expert Consult website for color version.) (From Mahanty S, MacLean JD, Cross JH. *Liver, Pathogens, and Practice,* 3rd ed. Philadelphia; Saunders: 2011, p 854–67.)

infection is found in the youngest age groups and in women; whereas intensity of egg excretion often increases with age and male gender.[80] The prevalence peaks in older persons, as shown in studies in China and Korea.[20,102]

Pathology and Pathogenesis

The epithelium of infected bile ducts reacts with desquamation, adenomatous hyperplasia, and metaplasia of goblet cells, accompanied by an increase in mucus production. The pathogenesis of the hepatobiliary damage may be due to the induction of an immunologic response in the host by mechanical action and secreted products from the flukes. Fibrosis and ductal dilation and obstruction are the consequence of the inflammatory reaction elicited by the parasites. Bile stasis in turn may lead to bacterial cholangitis and further inflammation in the bile ducts. The severity of the changes relates to the intensity of infection, host susceptibility, and number of reinfections. Chronic infection may lead to extensive periportal and periductal fibrosis, a process in which interleukin-6 mediated responses seemed to play a key role.[86,88,89]

The infection is a significant risk factor for cholangiocarcinoma in endemic areas.[87,88] Experiments in hamsters have shown that repeated infection with *O. viverrini* induces overproduction of nitric oxide, which may play a significant role in the development of cholangiocarcinoma through oxidative and nitrosyl DNA damage.[75] In addition, excretory and secretory products from *O. viverrini* induce proliferation of fibroblasts.[90] The excretory and secretory products induce the production of retinoblastoma and cyclin D1 proteins in the hamster model, both of which have been implicated in the mechanism of *Opisthorchis*-induced cholangiocarcinoma.[12] *O. viverrini* infections involve the gallbladder and may lead to complications such as gallbladder sludge, cholecystitis, and formation of gallstones.[67,68] The parasites may be found in the pancreatic ducts, where reactions of the epithelium are similar to those in the bile duct. Pancreatitis occurs infrequently in these liver fluke infections and is usually mild.

Clinical Manifestations

In endemic areas, infections may begin early in life and often are asymptomatic.[68,89] The occurrence of symptoms correlates with the intensity of infection. Patients with higher fluke burdens are more likely than those with lower burdens to have right upper quadrant pain, abdominal discomfort, and jaundice. They are also more likely to have abnormalities on ultrasound examination, such as intrahepatic bile duct dilation and periductal liver fibrosis.[80] Other findings may include weakness, malaise, and liver enlargement. A community-based study showed significant improvement of symptoms, laboratory test results, and ultrasound abnormalities after treatment of infected subjects.[76]

An acute febrile syndrome starting 2 to 3 weeks after exposure has been reported with *O. sinensis* and *O. felineus* infections.[35,88] Symptoms include fever, malaise, anorexia, diarrhea, and tender hepatomegaly. Eosinophilia, which is not as common in the chronic phase, is typically found during the acute illness.

Complications are more likely to occur in heavy infections. Relapsing cholangitis, cholecystitis, bilirubin gallstones, and pancreatitis all have been associated with infection.[68,80] Clonorchiasis has been cited as a cause of pancreatitis in individuals from endemic areas.[54] *O. viverrini* and *O. sinensis* are considered carcinogenic to humans and have been included in the World Health Organizations' list as group I carcinogens.[41] *O. viverrini* and *O. sinensis* are associated with cholangiocarcinoma in adults, and the former is presumed to be responsible for more than 60 percent of liver tumors in northeastern Thailand.[32]

Diagnosis

Symptoms of acute infection may develop 3 to 4 weeks before eggs appear in the stool. Immunologic tests are useful to establish the diagnosis during this phase. Antibody-based tests are in use in some endemic areas, but suffer from high rates of cross-reactions with antibodies to other parasites.[45,55,88] The sensitivity and specificity vary depending on the antigens used. ELISA using excretory and secretory products performs better than crude antigen enzyme-linked immunosorbent assay (ELISA), but cost precludes widespread use.[22,44] Demonstration of *O. viverrini* antigen in stools using a monoclonal antibody–based ELISA appeared to be specific and highly sensitive.[45,82,88]

In chronic infections, eggs are evident on fecal microscopy examination. The Kato Katz test is widely used but lacks sensitivity, especially in patients with very low parasite burdens. Concentration techniques such as the formalin-ether test are more sensitive than the Kato Katz.[6,34,35] Microscopy is useful in the clinical setting and in epidemiologic studies because it provides information regarding intensity of infection. Nonetheless, microscopic differentiation of *O. viverrini* and *O. sinensis* eggs is not easy. In addition, differentiation of these eggs from eggs of small heterophyid flukes is also difficult. Polymerase chain reaction (PCR)-based tests have shown promising results for the diagnosis of *O. Viverrini* and *O. sinensis*.[52,79] The loop-mediated isothermal amplification test, based on DNA polymerase with strand displacement at a constant temperature may be even more sensitive.[4,14,41,58]

Imaging studies may aid in diagnosis of these flukes. Ultrasound findings include intrahepatic bile duct dilation, increased periductal echogenicity, and gallbladder sludge.[23,68] Cholangiography often shows multiple cystic dilations of the ducts, elliptic or filamentous filling defects within the peripheral intrahepatic ducts, and intrahepatic duct haziness.[21] A combination of large cystic dilations and small cystic ectasias or mulberry-like dilations is considered diagnostic. The adult worms also may be visible on endoscopic retrograde cholangiopancreatography.

Treatment and Prognosis

All three *Opisthorchis* infections respond well to treatment with praziquantel.[33,35,63,88] The recommended dose is 25 mg/kg given three times for 2 days. A single dose of 40 mg/kg also can be used. At the recommended doses, praziquantel cures over 80 percent of infected people.[63] Side effects of headache and dizziness are common occurrences. Treatment may decrease the risk for development of cholangiocarcinoma in those infected. Preliminary studies suggest that there may be efficacy for tribendimidine.[85]

PREVENTION

The main barriers to prevention are deep-seated eating habits on raw or improperly cooked fish in endemic areas.[100] Thus, preventing human stool contamination of fish ponds and decreasing the snail population in these setting helps decreasing the prevalence of fishborne fluke infections. An approach in which infected human and other mammals are treated, sanitation is improved to avoid contamination of fishponds with raw human sewage, and health-promotion activities are carried out to decrease raw fish consumption is likely to have an impact on the incidence of infection.[83]

FASCIOLIASIS

Fascioliasis is a parasitic disease caused by the flukes *Fasciola hepatica* and *Fasciola gigantica*. With 91 million people at risk for acquiring infection, human fascioliasis is an important public health problem with an increasing incidence of human cases in 51 countries.[13,33,34,66,72] Fascioliasis is primarily a zoonosis of ungulates (e.g., cattle and sheep). Although humans are considered an incidental host, the epidemiology of the disease is driven by human infection in hyperendemic areas.

The Organisms

Fascioliasis is caused by two foodborne trematodes from the genus *Fasciola*, *F. hepatica* and *F. gigantica*. *F. hepatica* adult worms measure up to 30 mm in length and 13 mm in width. *F. gigantica* measures up to 75 mm.[66,88] During chronic infection adult parasites reside in the bile ducts, where eggs are produced. They reach the intestine through the bile and are excreted in feces. Eggs measure 130 μm in length and 90 μm in width and are indistinguishable from those of *F. buski*. After being incubated in water for several days, the ciliated miracidium hatches and penetrates the freshwater snail host, where it undergoes a complex cycle of asexual multiplication. Cercariae leave the snail and encyst on fresh-water vegetation, including watercress and alfalfa. These encysted metacercariae initiate infection when the mammalian host ingests the raw aquatic vegetation or water contaminated with metacercariae. The metacercariae excyst in the intestine. The larvae penetrate the intestinal wall and migrate from the peritoneal cavity to the liver. The developing worms penetrate the liver capsule and slowly burrow through the parenchyma to the bile ducts, where they mature into the adult worms. Adult *Fasciola* feed on liver cells and duct epithelium. The life span of the adult fluke in humans ranges from 9 to 13 years.

Transmission and Epidemiology

Epidemiologic studies suggest that human *Fasciola* infection is transmitted through ingestion of infected raw aquatic plants, such as watercress and alfalfa, and by drinking untreated water with metacercariae.[51,69,72] Herbivorous mammals, such as sheep, cattle, goats, and camelids, act as definitive hosts in nature. Fascioliasis has a worldwide distribution, with human infection reported from at least 51 countries in South America, the Caribbean, Africa, and Asia.[72] The number of human cases is estimated at over 17 million, with more than half of the burden of infection reported from the Andean region and the Caribbean.[33] More recent data suggest that those estimates may have significantly underestimated the burden of disease. For example, reports from Bolivia and Peru showed a prevalence as high as 70 percent in hyperendemic areas.[13] The highest fascioliasis prevalence in the Andean region is observed in children, whereas in the rest of the world the infection prevalence is more evenly distributed among different age groups. However, recent data suggest that fascioliasis is emerging as a serious public health problem in Vietnam, with thousands of cases diagnosed in recent years.[72,88,92] Similarly, outbreaks have occurred in Iran, with more than 17,000 clinical cases.[39,77,78]

Pathology and Pathogenesis

Fascioliasis has an acute phase caused by juvenile flukes that migrate through the liver parenchyma and a chronic phase caused by the adult flukes that start egg production in the biliary tract. The pathogenesis of acute fascioliasis is related to direct liver damage caused by the migrating flukes and to the inflammatory reaction triggered by the fluke antigens. Linear necrotic lesions containing eosinophils form as flukes progress through the liver parenchyma. Flukes that die before reaching the bile ducts may produce necrotic cavities that eventually evolve into fibrous scar tissue. During the chronic stage, adult worms in the bile ducts cause inflammation and adenomatous changes in biliary epithelium, leading to duct thickening and dilation. Ductal and periductal fibrosis occurs. The gallbladder and extrahepatic ducts may be invaded and undergo similar inflammatory and fibrotic reactions. Adult worms may migrate back into the liver parenchyma through eroded biliary epithelium and cause formation of abscesses. Liver cirrhosis has been described in severe forms of fascioliasis. The inflammation associated with infection is probably associated with the anemia and weight loss that occurs with fascioliasis.

Clinical Manifestations

It is estimated that 15 percent of fascioliasis cases have high-intensity infections. As with other helminthes, those with a heavy burden of parasites are more likely to be symptomatic.[34] Even those considered asymptomatic may suffer from anemia.[62] Thus, approximately 85 percent of *Fasciola* infections may remain subclinical and undiagnosed. Symptoms appear approximately 4 to 6 weeks after infection. The duration of this latent period depends on host response and the intensity of infection. The acute phase is characterized by right upper quadrant or generalized abdominal pain, tender hepatomegaly, fever, and anemia, typically associated with marked eosinophilia.[5,10,35,47,91] Sweating, dizziness, wheezing, and urticaria may occur. This stage lasts 1 to 3 months. The chronic form of the disease is associated with symptoms of biliary system obstruction. These symptoms frequently are identical to those of gallbladder disease, cholangitis, and pancreatitis caused by nonparasitic conditions. Elevation in alkaline phosphatase levels is a common manifestation.[5,10] Heavy and repeated infections eventually may cause liver damage sufficient to produce cirrhosis. Eosinophilia is not uncommon in chronic infections, but is usually low grade. Juvenile flukes that fail to migrate into the liver may wander about and cause ectopic fascioliasis. The most common ectopic localization of immature *F. hepatica* flukes is in the subcutaneous tissues of the thorax, back, and extremities but also has been observed in lungs, heart, brain, and intestinal wall.[88] Blancas-Torres reviewed a large series of fascioliasis patients (37 acute and 240 chronic) admitted to a hospital in Peru. A significant finding among these patients was the prevalence of weight loss (40%) and anemia (30%).[10] Severe acute disease may follow massive exposure and present with fever, eosinophilia, subcapsular hematoma, and tracks on imaging studies.[70]

Diagnosis

The acute manifestations of human fascioliasis may precede the appearance of eggs in the stool by 7 to 12 weeks. The triad of fever, abdominal pain, and eosinophilia combined with compatible exposures are helpful to suspect the diagnosis. Multiple immunodiagnostic tests are available to detect *Fasciola* during the acute phase of infection. Differences in sensitivity vary according to the antigens and antibodies used. The Fas2 ELISA test has a sensitivity of 92 percent and a specificity of 83 percent.[28] A commercially available sandwich ELISA using excretory or secretory antigens had a sensitivity and specificity over 95 percent when tested using serum of chronically infected individuals.[95] Serologic tests are also useful in the diagnosis of ectopic fascioliasis.

During chronic infection, *Fasciola* eggs may be detected in the stools. The Kato Katz and the rapid sedimentation tests are commonly used for microscopy diagnosis of fascioliasis.[6] These tests have low sensitivity, and testing multiple stool specimens is often required. False-positive stool examination results may occur if the patient recently ingested raw infected liver containing *Fasciola* eggs. Serum and stool antigen tests are available for diagnosis in veterinary medicine, and their use in humans is under study,[13] with pilot studies suggesting that they may be useful in human infections.[24,94] PCR-based tests are being developed for the detection and differentiation of *Fasciola spp.* PCR targeting the ITS-2 region of the ribosomal DNA gene has shown the highest sensitivity and specificity. A loop-mediated isothermal amplification test has been used to successfully detect *Fasciola* DNA with 10^4 times more sensitivity than conventional PCR in laboratory specimens. The loop-mediated isothermal amplification test could also differentiate *F. hepatica* from *F. gigantica*.[2]

Adult flukes may be seen on ultrasonography and appear as curvilinear lucent areas in the contrast medium in cholangiography. Endoscopic retrograde cholangiopancreatography may directly visualize the adult flukes, which are leaf shaped and bile stained. Eggs also may be identified in bile aspirates by microscopy. Radiologic imaging of the liver may demonstrate slowly evolving lesions, including track lines, small abscesses, and subcapsular hematomas.[16,27,47,56,71]

Treatment and Prognosis

Unlike other trematode infections, fascioliasis is relatively resistant to praziquantel. The drug of choice is triclabendazole at a dose of 10 mg/kg with a meal once or twice. The formulation manufactured for human use as Egaten is currently not available in the United States. Triclabendazole (Fasinex) has been used for many years by veterinarians for treatment of livestock in endemic areas. Anecdotally, it has been used safely in humans. However, resistance is emerging in isolates from livestock. Winkelhagen and colleagues[98] reported a possible case of triclabendazole resistance in an elderly sheep

farmer who failed several courses of treatment. Triclabendazole has been used successfully in a variety of open clinical trials in adults and children for both acute and chronic fascioliasis.[70,96] It is effective against both migrating flukes and established infections. Artemisinins have been used for the treatment of fascioliasis in two trials, with disappointing results.[49] Nonetheless, the combination of triclabendazole and artemisinins or ketoconazole showed promising results to overcome resistance in animal studies.[48] Nitazoxanide may be used to treat chronic fascioliasis.[29]

Prevention

Education and communication on safe growing of water plants for human consumption to avoid contamination with fecal material should be promoted.[72,88] Consumption of wild water plants in the field should be discouraged. Water purification systems should be implemented in highly endemic areas. The World Health Organization is promoting the use of mass treatment of children in endemic areas, but data are limited on safety and efficacy of this approach.[96,100]

LUNG FLUKE

PARAGONIMIASIS

The parasites of the genus *Paragonimus* are zoonotic parasites with felines, canines, and other carnivores as definitive hosts, snails as intermediate hosts, and crabs or crayfish as second intermediate hosts.[8,33,48,66,88] Over 40 species of *Paragonimus* have been identified, at least 8 of which have been recovered from humans. The species causing human disease vary by region.

The Organisms

The adult forms of *Paragonimus* form flattened leaf-life structures that measure about 7 to 16 mm long and 3.5 to 6 mm wide with anterior and ventral suckers.[8,66] The adult worms typically are located in the lungs of the definitive host. The ova are large (80 to 120 µm × 48 to 65 µm), yellow-brown in color, and contain a single operculum. Ova are shed into the bronchi and are either expectorated or swallowed and excreted in feces. After an incubation period of at least 2 weeks in fresh water, the free-living miracidia emerge and penetrate the snail intermediate host. After several weeks, the cercariae emerge and invade or are ingested by fresh-water crabs and crayfish, forming cystic metacercaria in the tissues. Humans and other mammalian hosts are infected by ingestion of undercooked crab or crayfish. Larvae released from the metacercaria penetrate the wall of the intestines and migrate through the diaphragm to reach the lungs. In some instances, the worms may lodge in ectopic sites within the abdomen, liver, subcutaneous tissue, or the central nervous system (CNS). The worms usually are found singly or in pairs within a capsule or cyst of reactive host tissue. Approximately 2 to 3 months are required from the time of ingestion until the worms are fully mature. Diploid forms reproduce sexually and triploid forms by parthenogenesis. In most infections, the worms die within 10 years; however, production of eggs for 20 years after the individual has left the endemic area has been reported.

In the past, most cases of paragonimiasis were attributed to infection with *P. westermani*, but molecular studies have revealed that more than nine different species of *Paragonimus* infect humans.[8,9,42,66] Molecular characterization has shown that typical pleuropulmonary infections in China, Japan, and Korea were largely due to *P. westermani*.[8] However, *P. skrjabini* (and the related *P. myazakii*) cause atypical clinical disease in those areas.[8,9,88] Although *P. westermani* is endemic in India and Southeast Asia, nearly all clinical isolates are *P. heterotremus*.[25,26,81,101] Endemic areas with *P. africanus* and *P. uterobilateralis* can be found in Central Africa (Cameroon and Nigeria)[3,74] and with *P. mexicanus* also the Pacific rim from Peru to Central America, with the major focus in Ecuador.[8,43] Endemic cases have also been increasingly recognized in Missouri and are due to *P. kellicotti*.[30]

Transmission and Epidemiology

The endemic areas for paragonimiasis are largely limited to areas where the ecology allows for infection of all of the hosts, including infection of fresh-water snails, spread to fresh-water crabs and crayfish, and ingestion of the crabs and crayfish by the definitive hosts.[8,66] Human infection is acquired by eating fresh-water crabs, crayfish, or shrimp that are raw, inadequately cooked, salted, or pickled. Recent cases acquired in the United States have been traced to ingestion of raw crayfish (*P. kellicotti*) or imported crabs (*P. westermani*).[11,57] A number of autochthonous cases have recently been described associated with freshwater canoe trips in which raw crayfish were ingested on a dare.[57] Infection has also been associated with ingestion of undercooked wild boar meat, with the boar serving as a paratenic host. There are also reports of infection from ingestion of water contaminated with metacercaria from crabs.

The global prevalence of human infection is estimated at over 20 million persons infected with 293 million at risk.[8,33,34] Overall, prevalence has been decreasing in much of east Asia such that disease is now rare in Japan, Korea, Taiwan, Philippines, and eastern China, which once were highly endemic.[8,34,60] Nevertheless, a recent national survey in China revealed a seroprevalence of paragonimiasis in 1.7 percent with disease found in 21 different provinces.[60] Disease appears to be increasing in some areas after construction of the Three Gorges Dam.[104] Paragonimiasis remains endemic in much of Southeast Asia (including Vietnam, Thailand, and the Lao People's Democratic Republic). For example, a recent study revealed seroprevalence ranging from 0 to 12.7 percent in parts of Vietnam[26] and disease is described in all countries of southeast Asia as well as eastern

India,[25,81] where more than half of children were seropositive in one focus. *Paragonimus* is endemic in central and western Africa, but most human cases are reported from Cameroon and Nigeria, with up to 14.8 percent of the population seropositive in some regions of southwestern Cameroon.[3,74] *Paragonimus mexicanus* is endemic in Latin America, with the primary focus in Ecuador and northern Peru, but case series have been reported from Colombia and Venezuela, in Central America, and as far north as Mexico.[8,15,43]

Pathology and Pathogenesis

Larvae are released after ingestion of ova. The larvae penetrate the duodenum and enter the abdominal cavity aided by excretory proteases.[8] Larvae may penetrate the diaphragm to the pleura soon thereafter or the larvae may linger in the abdominal cavity or liver. After penetration of the pleura, the larvae burrow into the lung parenchyma and lodge near larger bronchioles or bronchi surrounded by an exudate of neutrophils and eosinophils. In time, this inflammatory response around the parasite organizes into a fibrotic wall that may measure up to several millimeters thick. The cysts usually are 1 to 2 cm in diameter and often are filled with a brownish material that likely contains hematin. Ova are released via communications with bronchioles or bronchi into sputum. Complications of paragonimiasis include bronchiectasis, fibrosis, interstitial pneumonia, and secondary bacterial infections.

Parasites can also be found in ectopic locations such as the CNS or subcutaneously. Ectopic parasites are more common for species that are less well adapted to the human host, especially *P. skrjabini*. Up to 31 percent of cases may involve the CNS in some areas.[18,64] All areas of the brain and meninges are susceptible to invasion. The adult worms and the eggs cause areas of central necrosis and granuloma formation with dense collagenous walls surrounded by lymphocytes, plasma cells, eosinophils, and Charcot-Leyden crystals. The lesions vary in size and may be several centimeters in diameter and may appear cystic. Eventually, the wall may calcify. Spinal cord lesions are similar. The organisms can also cause a migratory subcutaneous nodule. Other sites at which worms may cause cysts or abscesses are the intestinal wall, mesentery, peritoneal cavity, liver, diaphragm, and myocardium.

Clinical Manifestations

Classical (Pleuropulmonary) Paragonimiasis

The classic presentation of paragonimiasis is with pleural or pulmonary disease.[33,35,66] Pulmonary disease is more common with species better adapted to the human host (e.g., *P. westermani*, *P. heterotremus*, or *P. africanus*)[25,26,60,74] than species less adapted to the human host (e.g., *P. skrjabini*).[8] Migration of the worms from the intestinal tract to the lungs does not usually cause symptoms, but has rarely been associated with fever, abdominal pain, diarrhea, and eosinophilia. However, if the parasites migrate across the liver, patients frequently present with abdominal pain and eosinophilia.[59] As the parasites enter the pleura, patients may present with fever, chest pain, dyspnea, cough, malaise, and night sweats. The pulmonary clinical manifestations are mainly a chronic cough. Cough may be dry or associated with sputum production, which may be described as mucoid, rust-colored or blood-streaked. Hemoptysis usually is intermittent and occasionally may be severe. Eosinophilia is a common finding in the early stages of infection but may return to normal over a period of months or years. Complications may include pneumothorax, pleural effusion, empyema, and pneumonia. The presence of hemoptysis and cavitary lung lesions can be confused with tuberculosis, but tuberculosis typically has more systemic symptoms (e.g., fevers, night sweats, and weight loss). However, systemic symptoms have been noted in most recent cases from North America.[57]

Nonclassic Presentations

Paragonimiasis may also infect other sites, including the subcutaneous tissues, brain, liver, abdomen, pericardium, and abdominal cavities. Extrathoracic disease is more common with parasites less adapted to the human host, especially *P. skrjabini*, but has been described from all endemic areas.[104]

Up to 31 percent of cases may involve the CNS.[18] Cerebral involvement is more common in children than adults. Most cases present with headache, nausea, and vomiting. Others may present with focal findings (e.g., aphasia, motor involvement, or sensory abnormalities). Patients also may have seizures, which are usually described as generalized. They may or may not have coexisting pleuropulmonary disease. Spinal cord lesions often are extradural and mimic mass lesions caused by tumors or infection.

Cutaneous paragonimiasis presents with subcutaneous nodules, which may be fixed or slowly migrate. Cutaneous nodules can account for up to 42 percent of cases in areas endemic for *P. skrjabini*, but are also noted in other areas. Worms recovered from these lesions are immature.

DIAGNOSIS

Most patients have pleuropulmonary symptoms, and initial evaluation includes a chest radiograph. Radiographs initially may be normal, but more typically demonstrate pleural effusions, nodules, or infiltrates.[25,40,46,53,74] Other radiographic findings include cavitations and fibrosis. Nodules and cysts can be found in any part of the lungs, but tend to localize in the periphery of the middle and lower lung fields. A common radiographic diagnostic feature is a "ring shadow." This finding represents the circular or oval thin-walled cyst with a crescent-shaped opacity along one side. Chest computed tomography (CT) findings vary by region (and thus likely by parasite species). Studies from Korea noted infiltrated and nodules in most cases.[53] Studies from Laos and India were more likely to show multiple cavitary lesions.[25,46] North American series noted more pleural effusions, pericardial involvement, and lymph nodes.[40]

Cerebral paragonimiasis may be seen as either an avascular mass or a hemorrhage on CT or magnetic resonance imaging.[1,18] Findings may include low-density, irregular shadows in most cases or, less frequently, hemorrhages. Either can be associated with edema and contrast enhancement. The ring enhancement may involve clusters of rings. In long-standing cerebral infections, the cystlike structures may calcify and be seen as a cluster of "soap bubbles." The individual oval or spherical bubbles may measure 2 to 40 mm in diameter, and a cluster of these structures may extend 10 cm.

Nearly all cases of paragonimiasis will present with eosinophilia. There can be some variability such that some authorities recommend repeating blood counts if eosinophilia is not present on the initial examination. Radiologic studies play a key role in diagnosis.

Pulmonary paragonimiasis is diagnosed definitively by finding the characteristic eggs in sputum or stool from a patient with symptoms suggesting the infection. Ova are more readily visualized with concentration or Ziehl-Nielsen staining.[84] Eggs are not present until 2 to 3 months after infection develops. Concentration techniques may help identify eggs in patients with light infections. Eggs have also been identified by percutaneous aspiration of lung nodules.[103] Several immunodiagnostic tests, including ELISA and immunoblotting have been developed, which may assist with confirming the presence of infections. Immunodiagnosis is especially useful in infections in which eggs are not demonstrated easily, such as in cerebral paragonimiasis. The immunoblot assay performed with a crude antigen extract of *P. westermani* has a sensitivity of 96 percent and specificity of 99 percent and is the serodiagnostic test of choice.[37] Antibody levels detected by enzyme immunoassay and immunoblot decline slowly after successful treatment, so antigen-detection systems may be a more useful approach to monitor treatment efficacy.[43] Tests that amplify parasite DNA, including loop-mediated amplification, may improve sensitivity, but are not widely available.[19]

Treatment and Prognosis

Praziquantel 75 mg/kg divided into three doses is given daily for 2 or 3 days.[33,35] Triclabendazole has been studied as an alternative treatment for humans infected with *Paragonimus* spp.[21] One study demonstrated 84 to 90 percent efficacy with single-day regimens of 1 or 2 doses of triclabendazole for the treatment of pulmonary paragonimiasis.[5]

The prognosis is good in most pulmonary infections, even if they go untreated, although symptoms may persist for many years. Treatment effectively resolves the pulmonary lesions and symptoms. The prognosis for CNS involvement depends on the location and extent of the lesions but is usually grave.

Prevention

The key in prevention is education of the population in endemic areas concerning the source of infection. Crabs and crayfish, prepared in a manner that transmits paragonimiasis, are delicacies in many parts of the world. However, education about preparation of these foods has led to dramatic reductions in the number of cases in Japan, Korea, the Philippines, and eastern China. Mass chemotherapy is being used to try to help prevent infections. Because paragonimiasis is a zoonosis, however, it is less amenable to control by mass treatment of human populations or improved sanitation.[100]

INTESTINAL FLUKES

Approximately 40 to 50 million people are thought to be infected by one or more of the 70 species and 14 families of intestinal flukes.[17,51,66] They are diverse morphologically, ranging in size from the *F. buski* (7.5 cm in length) to the tiny heterophyids (1 to 2.5 mm in length). Most cases cause few symptoms. However, heavy infections have been associated with a number of gastrointestinal symptoms. The most widely recognized organisms include *F. buski*, *Heterophyes* spp., *Metagonimus yokogawai*, and *Echinostoma* spp.

FASCIOLOPSIASIS

Life Cycle

Fasciolopsiasis is a foodborne intestinal zoonosis caused by *F. buski*, the giant intestinal fluke.[17,36,37,66,88] The adult fluke measures up to 7.5 cm in length and attaches to the duodenum and jejunum walls. The life span of adult *Fasciolopsis* is approximately 6 months. Egg production starts about 3 months after infection and these are 130 to 150 μm in length by 80 to 85 μm in breadth. A single parasite may excrete 25,000 eggs daily. The eggs are released in the feces, and after several weeks in fresh water, ciliated larvae hatch from the eggs and penetrate snails, where they reproduce asexually undergoing several larval stages. Cercariae emerge from the snail approximately 1 to 2 months later and encyst as metacercariae on a wide variety of aquatic vegetation and debris as well as on the water surface. Mammalian hosts are infected after ingestion of the metacercariae. Pigs are common reservoir hosts. Water chestnuts, caltrop, and water bamboo are common sources of human infection. Ingestion of larvae also can occur through drinking untreated water or handling water-derived plants (e.g., peeling contaminated water chestnuts with the teeth).

Epidemiology

Fasciolopsiasis occurs most often in Asia and the Indian subcontinent, with high prevalence rates recorded in

parts of south Asia and Thailand.[17,36,37,88,89] Pigs are the definitive host, and the prevalence of fasciolopsiasis is higher in areas where pigs are raised and aquatic plants are consumed. Fasciolopsiasis is most prevalent in school-age children, in whom high worm burdens are not uncommon findings.

Pathology

The parasites infect the duodenum and jejunum, but in heavy infections they can be observed in the stomach, ileum, and colon. Inflammation, ulceration, and small abscesses sometimes develop in the intestinal mucosa where the parasite is attached. Increased mucus secretion and mild bleeding can result. Light infections typically are asymptomatic. Massive infections can lead to intestinal obstruction and perforation. Complications such as malabsorption and protein-losing enteropathy, are common occurrences in heavy infections and can lead to generalized edema and ascites.

Clinical Manifestations

The severity of symptoms is correlated with the burden of parasites. Epigastric discomfort has been reported as early as 30 days after exposure. Diarrhea and abdominal pain may be intermittent and may occur separately. In heavy infections, nausea and vomiting may develop. Facial edema, anasarca, ileus, and intestinal perforation are encountered in severe infections. Eosinophilia with counts greater than 30 percent is not an uncommon occurrence. Leukocytosis and mild anemia may be noted.

In endemic areas, fasciolopsiasis contributes to malnutrition in children, especially when associated with other helminth infections. Fasciolopsiasis adds an additional burden to the host and in concert with other chronic helminth infections may be responsible for significant morbidity.

Diagnosis

The eggs of *Fasciolopsis* are demonstrated easily by routine fecal examination, but they are virtually indistinguishable from those of the liver fluke *F. hepatica* and the echinostomes. Epidemiologic information, such as travel history and exposure to sources of infection, may be helpful in determining the diagnosis. Because the life span of adult *Fasciolopsis* is short, anyone who has been out of an endemic area for longer than 9 months is not likely to have fasciolopsiasis. Incidentally, fasciolopsiasis can be diagnosed by upper endoscopy.

Treatment and Prognosis

Praziquantel 75 mg/kg divided into three doses given in 1 day is effective and safe. Infections treated early and most light infections, even when they are untreated, have an excellent prognosis. Heavy infections in children, especially when they are complicated by intestinal obstruction, edema, or concomitant secondary infections, portend a much poorer prognosis.

Prevention

Avoiding raw water-plants and untreated water may be a practical approach to prevent fasciolopsiasis. Cooking aquatic vegetation or immersing the plants or nuts briefly in boiling water usually is sufficient to prevent infection. Also, discouraging the use of human feces as fertilizer and promoting the institution of modern pig farming both can aid in the control of fasciolopsiasis. Successful efforts in health education or mass chemotherapy have reduced the transmission of this parasite in some endemic areas[88,97]; however, in areas where fasciolopsiasis was presumed controlled, such as Uttar Pradesh, reemerging infection has been reported.[7]

HETEROPHYIASIS

More than 11 different species of the family Heterophyidae have been reported to cause human infection.[17] *Heterophyes* spp., *Haplorchis* spp., and *M. yokogawai* are common human parasites, whereas other organisms are uncommon.

The Organism

Heterophyes spp., *Haplorchis* spp., and *M. yokogawai* adult worms attach to the mucosa of the small intestine. The parasites are minute, measuring 1 to 2.5 mm in length and less than 1 mm in width. They often burrow deeply into the mucosa. The eggs measure 26 to 30 μm in length and 15 to 17 μm in width. The eggs are nearly identical. Eggs excreted in the stool are fully embryonated. The snail intermediate host becomes infected by ingesting the trematode egg. After multiplication in the snail, cercariae emerge and encyst as metacercariae under the scales, skin, or in the muscle of a variety of fresh-water fish. After being ingested by the definitive host, the metacercariae are freed from their cysts and develop into adults in as little as 5 days.

Transmission and Epidemiology

Humans acquire the infection by eating fresh-water fish that is raw or inadequately cooked. Transmission may have a seasonal pattern, with the highest fish infection rates found during the summer.[61,93] Heterophyiasis occurs worldwide. Areas of endemic infection are Southeast Asia, the Middle East, the Nile Delta, China, Japan, Taiwan, the Philippines, and parts of the former Soviet Union. Many reservoir hosts, such as dogs, cats, and fish-eating birds, may play an important role in maintenance of infection in some endemic areas.

Pathology

The small heterophyid flukes cause variable degrees of inflammation in the intestinal wall.[17] Superficial inflammation and erosions are found at the sites of mucosal attachment. Eggs deposited beneath the mucosa cause eosinophilic granulomatous lesions. Eggs may invade the circulatory system through the intestinal capillaries or

lymphatics. Eggs may reach distant sites such as the heart, brain, and spinal cord, causing significant morbidity and even mortality. The embolized eggs induce a granulomatous response, with the eventual production of fibrosis in the infected areas. The complications of embolic heterophyiasis appear to be particularly frequent in the Philippines, where heart disease often is attributed to heterophyiasis.

Clinical Manifestations

Light infections without the deposition of ectopic eggs usually are asymptomatic, although eosinophilia may be noted. In heavier infections, epigastric pain, diarrhea, malabsorption, and weight loss may occur. Seizures may result from eggs carried to the brain. Congestive heart failure or arrhythmias may occur after cardiac involvement.

Diagnosis

Routine fecal microscopy may demonstrates eggs. Nonetheless, differentiating morphologically heterophyid eggs from those of the liver flukes may be difficult. Eggs recovered from patients who have been exposed more than 2 years before presentation are very likely to be from *Opisthorchis* or *Clonorchis*, because the life span of heterophyids is usually less than a year.

Treatment and Prognosis

Praziquantel 75 mg/kg/day in three divided doses for 1 day is the recommended treatment. With the exception of the complication of egg emboli to distant organs, the prognosis is excellent.

METORCHIASIS

M. conjunctus, endemic in North American; *M. bilis*, in Russia; and *M. orientalis*, in China and Korea, are members of the Opisthorchiidae family. They have a life cycle similar to that of the other opisthorchids. A wide variety of fish-eating mammals may serve as definitive hosts. This infection is a significant cause of morbidity and mortality in sled dogs in Canada. It is an occasional incidental finding on fecal examination in native communities in northern Canada. An outbreak of 19 cases of *Metorchis* infection was related to fish prepared raw as sashimi.[65] The epidemiology of metorchiasis outside North America seems to be far from an incidental illness. In areas where the epidemiology of *O. felineus* and *M. bilis* overlap, the difficulties differentiating *M. bilis* from *O. felineus* eggs have led to overdiagnosis of opisthorchiasis and the impression that it is much more common than metorchiasis. In Russia, serologic studies showed that metorchiasis is more common than previously recognized. In one study, 13 percent of subjects diagnosed as having opisthorchiasis had a positive ELISA for *M. bilis* and 37 percent had positive ELISA tests for both trematodes.[73] Similarly, national surveys in China have identify some foci of human *M. orientalis* infection in the Fujian province. The severity and duration of the symptoms probably correlate with parasite burden. The symptoms during acute infection are fatigue, upper abdominal tenderness, fever, epigastric abdominal pain, headache, weight loss, anorexia, nausea, diarrhea, vomiting, muscle pain, backache, cough, and rash.[65] The degree of eosinophilia and elevation in liver enzymes are proportional to the intensity of infection. Eggs are noted in stool 10 days after infection develops. Praziquantel is effective during acute metorchiasis and in the chronic phase.

CHAPTER 228

Schistosomiasis

Philip R. Fischer • A. Clinton White, Jr.

Approximately 230 million individuals are infected with parasites of the genus *Schistosoma*,[36,81,140,186,187] and another 700 million people are at risk for infection.[156,187,188] Many are unaware of their infection, although approximately 20 million people have severe disease with potentially fatal portal hypertension, urinary tract involvement, renal failure, and bladder cancer. Initial infection usually occurs during childhood. The prevalence typically peaks in the teen years, and, although most of the morbidity occurs in adults, symptomatic disease develops in millions of children.

There is historical evidence of schistosomiasis occurring as early as the second millennium BCE.[165,168] For example, *Schistosoma* eggs have been found in mummies from the 20th dynasty in ancient Egypt and in ancient China. In 1851, Theodor Bilharz identified the parasitic etiology of endemic hematuria. At the same time, the association between *Schistosoma* and Katayama fever was

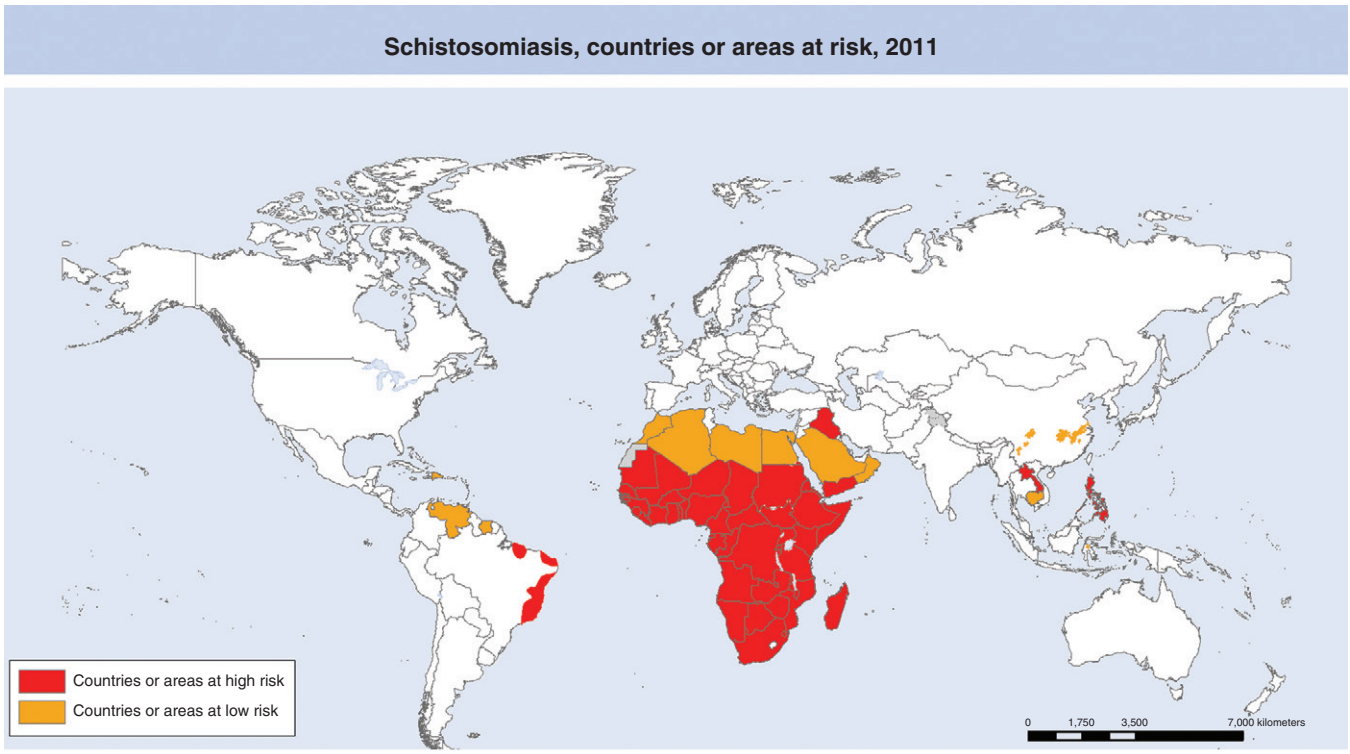
recognized in Japan. The complete life cycle was identified during the first decades of the 20th century. Before the development of effective curative medication in the 1970s, schistosomiasis was considered the "most dreadful of the remaining plagues of Egypt."[81,82] Nonetheless, it had been reported in 1919 that "it is now quite within the bounds of possibility that the disease may be largely controlled"[139]; even in this new millennium, success with disease control and eradication is still quite limited.

EPIDEMIOLOGY

Schistosomiasis is caused by helminth parasites of the class Trematoda, which includes the flukes. Schistosomes differ from other human flukes in that they live within the vascular system and have separate male and female sexes. Humans are the definitive host for five species within the *Schistosoma* genus.[165,168] *Schistosoma haematobium* is the cause of urinary schistosomiasis. *Schistosoma japonicum* and *Schistosoma mansoni* are common causes of disease resulting from infection of the intestinal vasculature. *Schistosoma mekongi* and *Schistosoma intercalatum* also cause infection along the intestinal tract but are found only in small geographic areas. Other mammalian *Schistosoma* spp. occasionally infect humans.

Each species of *Schistosoma* uses fresh-water snails as obligate intermediate hosts,[165,168] and the geographic distribution of *Schistosoma* is limited by the habitat of these snails (Fig. 228-1). Oncomelania snails transmitting *S. japonicum* live in the moist soil along slow-flowing streams and irrigation canals, limited primarily to parts of China, the Philippines, and Indonesia. The *Bulinus* snails associated with *S. haematobium* and the *Biomphalaria* snails associated with *S. mansoni* live in shaded, slow-flowing, shallow water. *S. haematobium* is seen primarily in tropical Africa, along the Nile River, and in the Middle East. *S. mansoni* is found across tropical Africa, along the Atlantic coast of South America, and on some Caribbean islands. *Tricula*, the snail host for *S. mekongi*, is limited to the Mekong River in Laos and Cambodia. *S. intercalatum* and its snail host *Bulinus* spp. are found only in Cameroon and the Democratic Republic of Congo. Most human infections occur when children come into contact with fresh-water streams, rivers, or lakes inhabited by infected snails (Fig. 228-2).[168] Thus, for most of the world, transmission of disease occurs during routine activities such as obtaining water for household use, bathing, fishing, and irrigation. Humans are infected by the fork-tailed schistosomal cercariae. Cercariae penetrate the skin with the aid of secretory serine proteases.[105,149] During penetration, the parasites lose their tails and modify their tegument to form the schistosomula stage. Schistosomas enter the bloodstream and then migrate to the lungs. They move from the pulmonary arterial circulation to the venous circulation without exiting the vessels. The parasites then travel through the systemic circulation



The boundaries and names shown and the designations used on this map do not imply the expression of any opinion whatsoever on the part of the World Health Organization concerning the legal status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries. Dotted and dashed lines on maps represent approximate border lines for which there may not yet be full agreement.

until they reach splanchnic vessels and gain access to the portal system.

During the course of a few weeks, the schistosomas develop into mature male and female adults that mate continuously.[167,168] Adult worms are 1 to 3 cm in length and usually live for 3 to 7 years. *S. haematobium* localizes to the venules of the urinary bladder, *S. japonicum* goes to the superior mesenteric vessels, and *S. mansoni* goes to the inferior mesenteric vessels. The gravid females migrate upstream to lay eggs near the bladder or intestines. Each adult female can produce hundreds (in the case of African species) to thousands (for Asian species) of eggs per day.[69] Most of the eggs become embedded in the walls of the peripheral vessel where they were laid. However, some of them flow with the blood and can stimulate reactions and cause disease at other sites. A localized granulomatous response allows the eggs to pass through the wall of the bladder (for *S. haematobium*) or the intestine (for other species) to be released in urine or stool. Released eggs mature in a week's time and then hatch to release miracidia. The miracidia penetrate the snail to continue their life cycle and eventually develop into hundreds of cercariae.

Infection is seen in children as young as 6 months; exposure to cercariae often is greatest in boys between the ages of 5 and 10 years.[81,87,165] In lakeside Ugandan villages, however, nearly half of the children are infected during the first 3 years of life,[124] and a study in a western Kenya town on the shores of Lake Victoria revealed infection in 14 percent of 1 year olds, 63 percent of 5 year olds, and 90 percent of 10 year olds.[180] The peak intensity of infection, as measured by excretion of eggs, occurs in children as young as 8 to 12 years in heavily infected areas and takes place during the teenage years in more lightly infected areas. The intensity and the incidence of excretion of eggs decline after the adolescent years, and hormonal changes during puberty are associated with increased resistance to infection.[93]

PATHOGENESIS AND IMMUNITY

Within hours of penetration of the skin, local erythema and inflammation may result from the activity of parasite proteases.[104,148,172] In individuals previously sensitized, a delayed immune reaction may cause papular or vesicular lesions.[91,165] Infiltration of the epidermis and dermis with a mixture of mononuclear cells and eosinophils causes papules. This reaction (termed *swimmer's itch*) is more pronounced for avian schistosomes, which are unable to penetrate into the human circulation and die in situ. During the initial migration of schistosomes through the lungs, patients may develop fever, pneumonitis, pulmonary infiltrates, and eosinophilia. However, these reactions resolve spontaneously.

Acute schistosomiasis typically begins 2 to 12 weeks after exposure, at the time the female parasites begin to produce eggs.[49,142] This condition is recognized more commonly with *S. japonicum* than with *S. mansoni* and rarely is described with *S. haematobium*.[91,165] Patients characteristically have marked eosinophilia, along with immunoglobulin (Ig)E and IgG antibodies to the parasites, consistent with an active T_H2 response.[91,165] However, studies suggest that proinflammatory cytokines play an important role.[46,119] The antibodies react with egg antigens, which cross-react with antigens from the cercaria or schistosomula stages.[10,75,76] During early production of eggs, the quantity of antigen exceeds that of antibody, and soluble immune complexes are formed. Immune activation and immune complex deposition lead to the clinical manifestations, including fever, myalgia, urticarial rash, and bloody diarrhea. Pulmonary nodules and infiltrates may be noted during acute infection.[39,150] In addition, acute infection can be complicated by ectopic egg production. Patients with acute *S. mansoni* or *S. haematobium* infection occasionally can have neurologic involvement.[31,55,133] Interestingly, acute disease occurs rarely in endemic populations, perhaps because of modulation of the immune response from exposure to parasite antigens in utero.

Chronic Schistosomiasis

Despite the fact that the adult worms live within the bloodstream, they cause little host response. The parasite surface incorporates blood group glycoproteins and major histocompatibility antigens and down-regulates expression of its own surface proteins, which may help the adults evade immune system attack.[66,130,157]

Chronic infection is characterized by localized granulomas surrounding the parasite eggs.[91,140,165] Excretory products of the eggs (termed *soluble egg antigens*) are the major antigens. The egg antigens are cytotoxic to host cells, such that infection of mice lacking T cells results in increased localized necrosis surrounding the eggs; the granulomas help protect the host from the ravages of the eggs. Interleukin (IL)-17 mediates the formation of granulomas in the liver.[196] The granulomas also facilitate transit of the eggs into stool and urine, as illustrated by the fact that immunodeficient hosts tend to have lower rates of shedding of eggs despite having high concentrations of eggs in tissues.[48,85,121] High levels of vasoactive endothelial growth factor and angiogenesis are associated with initial granuloma formation.[154]

The granulomas also contribute to the pathologic process. They are composed of a mixture of eosinophils, lymphocytes, macrophages, and granulocytes.[19] Late-stage granulomas also contain fibroblasts, collagen, and giant cells. Initially, antigen-presenting cells stimulate $CD4^+$ T cells to produce IL-2, tumor necrosis factor-α (TNF-α), and interferon-γ (IFN-γ).[120] Early expression of TNF-α plays a key role in the initial formation of granulomas.[5] A subsequent shift occurs toward production of T_H2 cytokines (e.g., IL-4, IL-5, IL-10, and IL-13) along with antibody.[131] This event is accompanied by eosinophil recruitment. IL-4 and IL-13 also play a primary role in the development of hepatic granulomas, and IL-13 expression is linked closely to the development of fibrosis in murine models.[34,35] Subsequent immunomodulation, largely mediated by IL-10 and transforming growth factor-β (TGF-β), results in downsizing of the granuloma and suppression of the inflammation.* When granulomas are limited to the intestines, the cytokine response is dominated by anti-inflammatory cytokines (e.g., IL-10 and TGF-β), and patients have few symptoms.[41] By contrast, patients with granulomas in the liver are more likely to be symptomatic. They express more inflammatory cytokines, including IL-13 and TNF-α. TGF-β also is associated with fibrosis in primate models,[52] whereas T_H1 cytokines (e.g., IFN-γ and IL-12) suppress fibrosis.[21,189,195] Macrophages activated by Il-4 and IL-13 (alternative rather than classic IFN-γ–based activation) seem to protect mice against schistosomiasis-induced inflammation and fibrosis with the acute infection while later promoting fibrosis with chronic infection.[13]

IL-13 in particular stimulates the formation of fibrosis in the portal tracts,[34] probably through the induction of expression of fibrosis-associated genes.[108] Portal fibrosis, in turn, leads to the development of portal hypertension (i.e., hepatosplenomegaly, ascites, and esophageal varices).[91] Death from hepatic schistosomiasis typically results from gastrointestinal bleeding. Overt bleeding is an uncommon occurrence in children, but it can occur in adolescents and young adults. In patients with isolated schistosomiasis, hepatocellular function is surprisingly normal.[19] Patients are thought to tolerate even gastrointestinal bleeding better than do those with cirrhosis. By contrast, progressive hepatocellular damage and rapid progression to liver failure develop in patients coinfected with hepatitis viruses, particularly hepatitis C.[9,38,84] The immunomodulation that develops in response to schistosomiasis is thought to suppress immune control of the hepatitis virus. Whether schistosomiasis-associated immune changes alter susceptibility to or expression of human immunodeficiency virus is unknown.[179]

Interestingly, patients with schistosomiasis are less susceptible to allergies.[27,178] Evidence indicates that asthmatics with schistosomiasis produce lower levels of IL-5 and greater levels of IL-10 than do asthmatics without schistosomiasis, and it is this suppression of T_H2 responses that might modulate the expression of asthma and atopic disease in patients with schistosomiasis.[7] Alternatively, it is possible that a common genetic predisposition alters the risk for subsequent development of both atopic disease and schistosomiasis.[12,110] A population-based study in Zimbabwe identified a negative correlation between atopy and the intensity of schistosomal infection in a village with a high frequency of schistosomiasis but not in a village with lower infection frequency,[145] indicating the interrelatedness of schistosomal antigenic stimulation and the development of allergic disease.

Several means exist by which schistosomiasis might be related to anemia, and the exact pathologic mechanisms are not fully understood.[60] At least sometimes, however, the anemia is due to inflammation rather than iron deficiency.[96] Generalized undernutrition is associated with

*References 8, 52, 58, 77, 111, 119, 155, 183.

schistosomiasis; proinflammatory cytokines (IL-1β) and generalized inflammation (as manifested by elevated levels of C-reactive protein) are contributing factors.[43] Even without acute inflammation, schistosomal infection and periportal fibrosis are associated with reduced vitamin A status and high oxidative stress (increased serum hydroperoxides).[17] Schistosomiasis-affected children have lower levels of regulatory T cells with altered cytokine responses; this seems to provide some protection against concurrent malaria infection.[109] Similarly, parasite-induced changes in the T_H1/T_H2 balance are hypothesized to explain how young children with underlying schistosomiasis are less likely to develop malaria.[110]

Approximately 40,000,000 women of child-bearing age are infected with schistosomes. Although mechanisms are not clear, some evidence indicates that schistosomiasis during pregnancy is associated with decreased birth weight and a higher risk for preterm delivery.[61]

Urinary Schistosomiasis

Genital and urinary schistosomiasis also is the result of granuloma formation. Severity of disease correlates with increased production of TNF-α and decreased production of IL-10.[92] Direct inflammatory responses to eggs along the ureters or from obstruction to ureteral drainage caused by space-occupying granulomata in the bladder wall block ureteral emptying.[88,158] All tissue layers may be involved, but pathologic changes are usually most extensive in the submucosal layer.[86] Abnormal ureteral flow, dilatation, and hydronephrosis develop.[158] In some communities where *S. haematobium* is common, ureteral deformities demonstrable on intravenous pyelography are noted in half of affected children and hydronephrosis develops in more than 10 percent.[89] Eventually, scarring and calcifications form and may be associated with chronic hydronephrosis, even with resolved or light chronic infection.[92,158] The hydronephrosis and urinary stasis predispose patients to chronic bacteriuria and urinary tract infections.

In *S. mansoni* infection, immune complexes may mediate glomerulonephritis, as evidenced by the finding of schistosome-derived immune complex deposits in glomeruli.[14,160] Nephrotic syndrome has been reported in association with chronic schistosomiasis.[113,114] Amyloid deposits have been found in the kidneys of children with chronic schistosomiasis, and this condition probably is caused by immune responses that are altered by the chronic parasitic infection.[15,181]

Squamous cell carcinoma of the bladder is a common occurrence in areas of heavy infection with *S. haematobium*, but otherwise it is a rare form of bladder cancer.[92,158,165] The prolonged irritation of bladder epithelium by schistosome eggs and the resulting immune response are thought to trigger hyperplasia and subsequent malignant disease.[97] In an animal model, direct exposure to schistosomal antigens stimulates increased proliferation and decreased apoptosis of endothelial cells along with downregulation of tumor suppressor p27 and upregulation of antiapoptotic molecule Bcl-2.[23] This condition could be aggravated by urinary stasis in the bladder with secondary increases in pH that favor malignant transformation of epithelial cells. Carcinogenic tryptophan metabolites also have been postulated to link the nutritional activities of parasites near the bladder with subsequent carcinogenesis. Schistosoma-related bladder cancers have biomarker prevalence different from those of nonschistosomal bladder cancers, and this might have an impact on eventual treatment choices.[2]

CLINICAL MANIFESTATIONS

The main clinical manifestations of schistosomiasis vary with the stage of the parasite's life cycle and also differ among species. Many patients remain asymptomatic. Patients with asymptomatic schistosomiasis may be identified during community screening programs in an endemic area, through immigrant or returned traveler evaluations in a nonendemic area, or when diagnostic tests such as urine or stool microscopy are performed to evaluate other, seemingly unrelated symptoms. The minority of infected children, those with heavy infections, are most likely to develop early symptoms and also are at greatest risk for subsequent major health complications.

Cercarial Penetration

Within a few minutes of coming into contact with cercariae, some children develop pruritus. This response to initial contact with the parasite occurs more commonly in nonimmune visitors to endemic areas than it does in indigenous residents of endemic areas, but it seems to be more pronounced after repeated exposure to cercariae than on the first exposure. It may occur after contact with any of the human *Schistosoma* spp. but more commonly results after contact with the cercariae of avian schistosomes. An erythematous and sometimes papular rash may develop.[91,165] The rash usually subsides during a period of 2 to 10 days without scarring, regardless of whether specific treatment is given.

Acute Schistosomiasis (Katayama Fever)

Acute schistosomiasis, referred to as Katayama fever, typically begins 2 to 12 weeks after exposure, when the adult worms begin to produce eggs.[48,80,142] Clinical manifestations of acute schistosomiasis usually include high fever, chills, myalgia, headache, and a general ill appearance.[46,49] An urticarial rash, which may include giant urticaria, and diffuse lymphadenopathy may be seen.[138,198] Cough, rales, and pulmonary infiltrates may be noted, even in the absence of fever.[39,150] Gastrointestinal symptoms of anorexia, abdominal pain, and loose stools sometimes are observed. Bloody diarrhea may be seen acutely with heavy infections by *S. japonicum* and *S. mansoni*. Tender hepatomegaly and mild splenic enlargement develop in approximately 30 percent of children with Katayama fever. Some reports suggest that myelopathies are a common accompaniment of acute schistosomiasis.[55,133] Genital symptoms (primarily hematospermia) also are frequent initial symptoms.[40,136] Marked eosinophilia often is seen with acute schistosomiasis.

Urinary Schistosomiasis

Hematuria is the classic finding of *S. haematobium* infection.[25,47,88,165,185] In some highly endemic areas, for boys nearing puberty not to display this evidence of "male menstruation" is considered abnormal. Typically, hematuria results from the release of blood from irritated, inflamed areas around granulomas in the bladder wall as the bladder contracts during micturition.[158] Thus, the blood is most obvious at the end of the urine stream ("terminal hematuria"). The hematuria usually is not associated with pain or discomfort, but dysuria can be present.[1,25] With chronic infection in children who either were not treated initially or were reinfected, obstructive uropathy can develop. In community surveys in endemic areas, as many as 40 percent of children were found to have significant renal or ureteral abnormalities (or both).[1,73,182] Hematuria and dysuria occur more commonly in children than in adults, presumably because they have heavier parasite loads. However, hydronephrosis, which develops more slowly, is seen more often in adults.[88,89,118,158]

Bacterial urinary tract infection may coexist with urinary schistosomiasis, probably secondary to obstruction of urinary outflow.[158] Chronic infection can lead to renal failure. Obstructive uropathy, with or without incident or recurrent urinary tract infections, can lead to loss of renal function. Children with schistosomal infection also can have glomerulonephritis and nephrotic syndrome. Bladder cancer, when it occurs, typically develops in the setting of untreated, heavy chronic urinary schistosomiasis.

Genital Schistosomiasis

Studies have emphasized the genital tract as an important site of schistosomiasis in both men and women.[28,98,133,134] In women, egg granulomas may be found in the cervix, uterus, or fallopian tubes.[53,98,99,134] Cervical irritation and ulceration, vaginal bleeding, or ectopic pregnancy may develop. Genital schistosomiasis can be confused with cancer.[170] Adolescent boys may have involvement of the prostate and seminal vesicles.[98,136] Eggs were noted in semen from 43 percent of men in an area endemic for *S. haematobium*.[98] The main clinical finding is hematospermia,[98] which may occur with acute infection or during chronic disease. In Africa in particular, genital schistosomiasis may be a cofactor in transmission of human immunodeficiency virus infection.

Intestinal Disease

Most children with intestinal schistosomiasis do not have intestinal symptoms.[164,165] Thus, even finding eggs in stool does not mean that symptoms are related to the schistosomiasis.[71] Nonetheless, both the small and large intestines may be involved with schistosomal disease. Irritation of the bowel wall from inflammatory reactions induced by eggs may lead to diarrhea that sometimes contains blood or mucus.[32,33,164-166] Crampy abdominal pain and generalized malaise may occur. Endoscopy can reveal granular inflammation with hyperemic areas, ulceration, and hemorrhage. Polyps, which may develop around granulomas, may be identified by contrast radiography or endoscopy. Protein-losing enteropathy and blood loss can result in malnutrition and iron deficiency, especially in cases with significant small bowel disease. The role of schistosomiasis in malnutrition was illustrated by studies of mass chemotherapy, which resulted in improved nutrition and a lower prevalence of anemia.[11,125,171]

Hepatosplenic Disease (Hepatomegaly, Splenomegaly, and Portal Hypertension)

The life-threatening complications caused by *S. japonicum* and *S. mansoni* are the result of eggs that remain in the venous vasculature and migrate back to the liver.[19] Egg burden seems to be the greatest predictor of hepatic involvement with schistosomiasis, but some link with human leukocyte antigen type has been suggested.[115,116,152,184]

Children with compensated disease initially have few symptoms. These symptoms may include anorexia, malaise, and abdominal fullness.* Children have hepatomegaly even without significant portal hypertension. The hepatomegaly generally is firm and either minimally tender or nontender. Splenic enlargement usually is noted as well. Liver function is affected only late in the course of hepatic schistosomiasis, so jaundice and liver enzyme elevations are unusual findings.

As fibrosis develops around eggs in the liver, portal hypertension ensues. Liver function usually remains intact, but esophageal varices can cause death during the late adolescent and early adult years.[19,33,127] Ascites gradually develops during a period of years, and the spleen may become very large. Bleeding esophageal varices are a common cause of demise in individuals who had heavy schistosomal infections in childhood. Such patients may come to medical attention for melena or hematemesis. Initial episodes are well tolerated. However, with progressive liver decompensation, variceal bleeding can be fatal.

Children with severe hepatosplenic schistosomiasis do not grow as well as other children. Debate has ensued about whether this deficiency is due to a direct effect of the parasitic infection or poor nutritional intake caused by poor general health. Some recent data suggest that a decrease in insulin-like growth factor–1 activity is linked to hepatic schistosomiasis.[129] Extensive formation of hepatic granulomata may hinder the liver's structure and function in such a way that growth-promoting factors are not produced normally.

Pneumonitis and Cor Pulmonale

Sometimes, children initially have low-grade fever and cough as schistosome larvae migrate through their lungs. This condition can occur with an initial heavy infection (when eggs will not be detectable) or a heavy reinfection (when eggs will be detectable in urine or stool from the preceding underlying infection). This larval pneumonitis

*References 19, 33, 94, 127, 136, 185.

can be manifested on lung examination as basilar rales and wheezing.[39,150] Radiographs may show basilar mottling in the lung fields. Eosinophilia is a common occurrence with this type of pneumonitis. Resolution, even without treatment, usually occurs in 2 to 4 weeks. Similar symptoms also may be seen as a reactive pneumonitis when patients with heavy parasite burdens are treated.

In children with advanced hepatosplenic schistosomiasis and portal hypertension, eggs may bypass the liver and flow from the abdominal and pelvic veins into the small lung vessels. Localized granulomas form around eggs lodged in the lungs. Over time, children may be subject to fatigue, cough, and right-sided heart failure. Medical therapy stops the progress of disease and may decrease the ongoing inflammatory responses, but right-sided heart failure, once it is established, is not fully reversible.

Central Nervous System Involvement

Neurologic manifestations of schistosomiasis may be dramatic, even if not common.* Worms do not always follow the typical routes described for urinary and intestinal schistosomiasis. On occasion, worms migrate to cerebral blood vessels. Production of eggs in that location can cause seizures and headaches in children.[133,151] Sometimes, optic field defects and dysarthria are noted; these findings seem to result from localized space-occupying inflammatory reactions that develop around worms or eggs. Magnetic resonance imaging (MRI) evaluation reveals a mass or masses of multiple intensely enhancing nodules.[106] Spinal fluid pressure may be elevated, and both protein concentrations and lymphocyte counts in spinal fluid may be increased. This cerebral schistosomiasis occurs more commonly with *S. japonicum* infection[56] and is thought to develop in as many as 2 percent of infected children.

S. mansoni infection and, to a lesser extent, *S. haematobium* infection can produce eggs that embolize to the spinal cord. The eggs or associated granulomas can cause transverse myelitis. Paraplegia along with urinary and fecal incontinence often is the initial problem in children with spinal schistosomiasis.[55,151]

Chronic or Recurrent Salmonellosis

In endemic areas, some children have salmonellosis and schistosomiasis concurrently and experience chronic low-grade fever, fatigue, malaise, and poor growth.† Blood cultures frequently demonstrate *Salmonella* bacteremia, but stool may not contain these bacteria. Some children have chronic *Salmonella* bacteriuria. Sepsis and mortality are unusual findings despite these persistent bacterial infections. Relapse of the *Salmonella* infection occurs commonly unless the coexisting schistosomal infection is treated. The bacteria are thought to hide within the parasitic worms, where antibiotic penetration is poor, and thereby evade host defenses.

†References 65, 94, 95, 137, 147, 192.

DIAGNOSIS

A clinical diagnosis of schistosomiasis should be entertained in the presence of typical clinical features. These features might be as obvious as painless hematuria in a child in a region endemic for *S. haematobium*, or portal hypertension may be noted late in the second decade of life in an otherwise healthy adolescent from an area known to be endemic for *S. mansoni* or *S. japonicum*.[136,149] The other clinical findings described also should prompt the clinician to consider a diagnosis of schistosomiasis when the child has resided in or traveled through a *Schistosoma*-endemic area.[169] In traveling children, the index of suspicion must be particularly high because patients may be asymptomatic or have atypical symptoms, they may not have clear history of exposure to contaminated water, and parasitologic examination findings often are negative.[18,136]

Outside endemic areas, reinfection is not expected. Thus, a reasonable approach is to test all children, including asymptomatic children, who have returned or emigrated from an endemic area where they had potentially significant exposure to fresh water. Such testing would involve all travelers who swam in, waded in, or even touched suspicious water, and it could involve immigrants who have spent long periods in endemic areas. Certainly, any child outside an endemic area who has even a remote history of having had possible contact with cercariae and clinical findings suggestive of any form of schistosomiasis should be tested. Testing is appropriate because even late therapy can favorably alter the course and outcome of schistosomiasis. In some highly endemic areas, diagnostic testing is of limited feasibility, questionable reliability, or both, and curative medications are readily available. In such settings, establishing a proved diagnosis might be less necessary. For example, in a highly endemic setting, a urine paper strip test result positive for hematuria could provide sufficient suspicion of infection to warrant administration of specific antischistosomal therapy. In populations with known high rates of infection, mass treatment (without expensive diagnostic testing) is reasonable.

In established heavy infections, eggs usually are readily apparent on microscopic examination of urine or stool. For lighter infections, concentrating techniques are useful. Urine can be centrifuged and filtered to increase the yield of eggs. The result of urine examination is most likely to be positive when urine is voided at midday and when it is collected at the end of the urine stream. In the event of high suspicion and negative urine findings, bladder wall biopsy can be performed. The procedure usually is not necessary, however, because urine microscopy, especially with filtered or concentrated samples, generally is positive. Examination of multiple samples increases the yield.

The eggs of *S. haematobium* and *S. mansoni* are approximately 90 mm in diameter, whereas the eggs of *S. japonicum* and *S. mekongi* are somewhat smaller. As demonstrated in Figure 228-3, identification of species is aided by observation of the spine—small for *S. japonicum* and *S. mekongi*, at one end for *S. haematobium*, lateral for *S.*

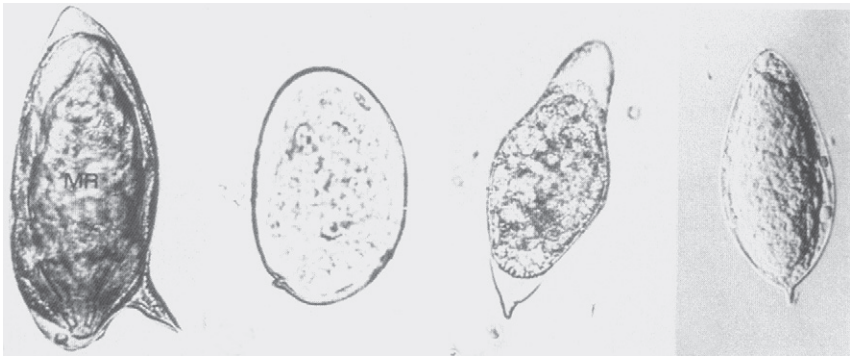

FIGURE 228-3 ■ Human schistosome eggs. **A,** *Schistosoma mansoni.* **B,** *Schistosoma japonicum.* **C,** *Schistosoma intercalatum.* **D,** *Schistosoma haematobium.* (From Mahmoud, A. A. F., editor. *Schistosomiasis.* London, Imperial College Press, 2001. Reprinted with permission.)

mansoni, and broad at each end for *S. intercalatum*. Eggs usually are detectable in voided urine. Plain radiographs might demonstrate some calcification in the bladder wall around chronic granulomas. Cystoscopy, if it is performed, reveals bladder wall hyperemia and, subsequently, nodular lesions and fibrosis that give rise to "sandy patches" on the bladder wall. Granulomas may protrude from the bladder wall into the lumen. Both edema and granulomas may be seen obstructing ureteral orifices.

In light infections, examination of stool or urine samples may not reveal ova because of intermittent or low-volume shedding. Thus, negative stool or urine test results do not adequately rule out intestinal schistosomiasis.[19,136] When stools repeatedly are negative for ova, rectal biopsy may be performed. Samples may be obtained by random punch biopsy, but the yield is increased when samples are taken from inflamed sites under direct visualization. Eggs are detected in unstained smears made by pressing the tissue sample between a coverslip and a glass slide, but eggs also can be seen with standard histologic stains.

Nonviable eggs may be excreted for months or years after therapy has been successful. With good medical treatment, eggs usually are not viable when they are passed more than a week after the initiation of therapy. With ineffective treatment or reinfection, however, viable eggs may continue to be passed. On microscopic examination, living ova contain transparent miracidia within the egg, which often are motile. For further documentation of their viability, the eggs may be hatched by placing them in fresh water exposed to light for 20 minutes; observation with a hand lens then can reveal swimming miracidia.

Serologic tests may be needed in acute infection, which may occur before the eggs are excreted or with eggs in ectopic locations.[72,174] For travelers with limited exposure and the likelihood of having either an acute or a limited chronic infection, serologic examination is the main diagnostic tool. A common screening serologic test is the Falcon assay screening test–enzyme-linked immunosorbent assay (FAST-ELISA) using *S. mansoni* adult worm microsomal antigen.[175] This test also cross reacts with *S. haematobium* but is less sensitive for *S. japonicum* or *S. mekongi* infection. Indirect hemagglutination tests are 70 to 80 percent sensitive for Katayama syndrome, and ELISA tests do not add to the diagnostic value when an indirect hemagglutination test has already been positive.[142] The species can be confirmed by use of an immunoblot assay (enzyme-linked immunotransfer blot).[174] An immunoblot assay also is available for *S. japonicum*. New tests hold promise in easily identifying incriminating schistosomal antibodies in serum[194] and urine.[51] Antigen-detection assays may be helpful.[3] In a small study of European travelers with acute schistosomiasis from Rwanda, serum DNA detection performed better than parasitologic and serologic tests in confirming the diagnosis.[37]

Ultrasonography is the main imaging procedure used in schistosomiasis.[73] It can document involvement of the portal and urinary tracts and, in selected cases, be diagnostic of schistosomiasis. Ultrasonography can identify bladder polyps, ureteral dilation, hydronephrosis, and calcifications within the urinary tract. When resources are available, an ultrasound evaluation of the urinary tract should be performed in any child found to be infected with *S. haematobium*. Ultrasonography can be readily implemented in clinical settings in developing countries to follow lesions of urinary schistosomiasis.[20] For children with persistent urinary symptoms (i.e., dysuria, suprapubic pain, and hematuria) despite having received good medical treatment, cystoscopy should be considered, in part to screen for bladder cancer. Other radiographs and tests of renal function and excretion generally are not indicated unless the ultrasound evaluation reveals significant urologic disease.

Portal ultrasonography is the imaging study of choice for hepatic involvement. The presence of periportal fibrosis with thickening of the portal tracts and vein walls (so-called clay pipestem or Symmer fibrosis) correlates with parasite burden and hepatic disease. In experienced hands, schistosomiasis can be distinguished reproducibly from cirrhosis and other chronic liver diseases.

MRI is helpful in diagnosing neuroschistosomiasis.[56] A variety of cerebral changes may be identified; although not specific for *S. japonicum* neuroschistosomiasis, large masses containing enhancing nodules may be seen in the brain.[56,106] Focal cerebral white matter hyperintensities and hyperintense basal ganglia may be seen in children with hepatosplenic schistosomiasis even when they do not have overt neurologic symptoms.[112] Spinal schistosomiasis, usually caused by *S. mansoni* or *S. haematobium*, can cause spinal pseudotumors with heterogeneous

enhancement as well as signal changes extending up and down the spinal cord from the thoracic level.[44,74]

TREATMENT

Optimal treatment of schistosomiasis varies with the stage of the disease. Cercarial dermatitis resolves spontaneously and requires no antiparasitic treatment. Oral antihistaminic agents, however, may be given for severe itching. Medical therapy for schistosomiasis caused by the human schistosomes is effective and well tolerated, without significant complications. No good medical reason exists to allow schistosomiasis to go untreated. The cost of therapy, however, is a limiting factor in resource-limited areas of the world. Several medications can be considered for curative treatment.

Praziquantel, a mixture of stereoisomers of pyrazinoisoquinoline ring structures, is a broad-spectrum oral anthelmintic agent that is effective against each of the five human schistosome species. The mechanism of action was thought to involve unmasking of parasite antigens with subsequent killing by the host immune response.[24] However, patients with acquired immunodeficiency syndrome respond well to praziquantel, raising questions about this hypothesis. Praziquantel is given in divided doses on a single day as full curative treatment. For infection with S. *haematobium*, *S. mansoni*, and *S. intercalatum*, the dose is 40 mg/kg in two divided doses given on the same day. For children infected by *S. japonicum* or *S. mekongi*, the recommended dose has been 60 mg/kg in three divided doses given on the same day.[4,6,143] Recent evidence, however, suggests that 40 mg/kg might be adequate for *S. japonicum* as well.[126] Heavily infected children sometimes experience nausea, vomiting, and abdominal cramping with treatment. Rare side effects, including headache, pruritus, bloody stools, and fever, are transient and resolve within 1 to 2 days after the initiation of treatment. Because praziquantel primarily kills mature adult worms,[68] repeat testing and/or a second course 6 to 12 weeks later is recommended for the treatment of acute infection.[141] In endemic area settings of school-based and community-based mass treatment, adding a second dose of praziquantel 2 to 8 weeks after the initial dose improves reduction in egg counts.[90] Praziquantel is effective in more than 90 percent of treated children. Some studies suggest that resistance may be emerging.[101,102] However, those studies were performed in areas with frequent reinfection and with high parasite burden. Thus, the poor response may be due to the fact that juvenile forms are not as susceptible to praziquantel. Recent work suggests that praziquantel is still effective in endemic areas,[153] and evidence is emerging that combining praziquantel with either artemether or artesunate might improve its efficacy.[107] Studies from nonendemic areas continue to demonstrate excellent efficacy.[185] In addition to curing infection, treatment with praziquantel is associated with improved growth and reduction in anemia.[42] In endemic areas with high rates of infection, school-based and community-based (when many children in the area do not regularly attend school) treatment strategies (without confirmatory diagnostic testing) are effective; cost issues, however, raise concerns of program sustainability.[62,90]

An alternative treatment effective only against *S. mansoni* is oxamniquine, a tetrahydroquinoline compound.[162] The mechanism by which this agent acts is unknown. The effective dose has varied with the geographic origin of the schistosomal infection, but some resistance has been reported. Current recommendations are that children treated with oxamniquine be given 40 to 60 mg/kg divided into two doses administered on 1 day or four separate doses given during the course of 2 days. Mild side effects include nausea, headache, and fever. Seizures are a rare side effect, so administration of this medication should be avoided in children with seizure disorders. Cure rates of more than 90 percent are reported with oxamniquine.

Metrifonate is an organophosphate compound that causes paralysis of the parasite. It is 70 to 80 percent effective against *S. haematobium* when used at a dosage of 10 mg/kg orally once every 2 weeks for 6 weeks. It does decrease the child's own plasma and erythrocyte cholinesterase activity, but actual cholinergic symptoms seldom occur. This medication is less expensive than the other options, but it generally is not used when praziquantel is available.

Medical therapy usually is effective for children with schistosomiasis,[144] even with advanced disease.[103,146,161,193] Clear improvement in the patient's disease burden occurs when treatment is given. Even established uropathy and portal hypertension often are reversible.[105,146,161] Surgical procedures usually are reserved for children with complications related to long-term infection, such as persistent portal hypertension. Propranolol prophylaxis and sclerotherapy or banding can reduce rebleeding from esophageal varices.[50] Some cases require surgical decompression of portal hypertension. Splenorenal shunts are associated with high rates of hepatic encephalopathy. Comparative studies suggest that in experienced hands, esophagogastric devascularization with splenectomy is the procedure of choice.[57,64]

Systemic steroids may be useful for severely ill children with Katayama fever or severe larval pneumonitis. Treatment of neuroschistosomiasis often involves a combination of corticosteroids and praziquantel, with surgery being reserved for those with medullary compression or hydrocephalus.[141] The role of steroids is significant[55,59] but controversial[30] and incompletely tested. Some experts suggest that glucocorticoids be started before the initiation of antiparasitic therapy, to prevent increased inflammatory responses triggered by dying worms.[141] Phenobarbital and phenytoin (but not levetiracetam) can alter metabolism of praziquantel; when used for neuroschistosomiasis-induced seizures, these medications might prompt upward adjustment of the praziquantel dose.[141] Corticosteroids have not been proved effective treatments in other forms of the disease.

PREVENTION

Schistosomiasis has been considered controllable or even eradicable for nearly 100 years.[139] Nonetheless, control is

still not quite within reach. Further multifaceted interventions are needed if we are to be rid of the scourge of schistosomiasis.[78,139]

Travelers and expatriates in endemic areas can prevent disease by limiting exposure to infectious fresh water. In endemic areas, they should avoid swimming in freshwater streams and lakes. In addition, the cercaria can be eliminated by chlorination or by allowing water to settle for 24 hours before bathing or washing.

The use of effective medical therapy coupled with improved urine and stool hygiene has the potential to eradicate schistosomiasis from endemic areas.[186] Elimination of the snails that serve as intermediate hosts also would be effective, but attempts at implementation of programs administering molluscicides have been unsuccessful to date. Historically, national control programs in China focusing on snail control, sanitation, and improved water supplies led to sustained reductions in infection rates, even apart from the influence of chemotherapy.[177,190] For specific populations, health education can lead to significant favorable changes in knowledge about the illness, water-exposure activities, and reinfection rates in school-age children.[70] Recently, control efforts have focused on mass chemotherapy, with particular emphasis on school-based therapy.[11,71,125,128,186] Similar treatment of preschoolers, especially combined with nonpharmacologic control efforts, is also effective.[122,163] Treatment programs in which the entire school-age population is treated, typically with praziquantel, have resulted in overall improvement in levels of nutrition and in a reduction in the prevalence of anemia. In areas where reinfection commonly occurs, however, the effects of mass treatment programs are of limited duration, and treatment must be repeated every 6 months to 1 year. Sadly, only about 10 percent of persons who could benefit from antischistosomiasis treatment are able to receive it each year.[78] Sustainability of national control programs and of favorable outcomes remains challenging in Africa.[63,83,54,79]

Several studies suggest that artemisinin derivatives can prevent development of infection and decrease the worm burden in those exposed to *S. mansoni* and *S. japonicum*.[100,107,140,176] With ongoing exposure to cercaria, prophylactic artemether or artesunate may be given as a 6 mg/kg dose every 1 to 2 weeks.[107] However, these medications are less effective for chemotherapy than is praziquantel,[22,45,141] probably because parasitologic activity is limited to the juvenile forms. Furthermore, the public health role of chemoprophylaxis in the prevention of infection has not been established.[141]

Immunization of experimental animals with irradiated cercariae can prevent experimental schistosomiasis.[159] Thus, development of a vaccine to prevent human schistosomiasis is theoretically possible. Several potentially protective antigens have been identified on schistosomes, and they are being used as targets for vaccine development. Animal studies with the Sm-p80 vaccine show promise with some favorable effects on worm reduction, worm egg production reduction, and decreased acute schistosomiasis.[156] Murine studies with Sm-TSP-2 show some efficacy, and chimerization with a hookworm vaccine antigen (Na-APR-1) increases the antischistosomal effectiveness of the vaccine.[132] Human studies are in progress with Sh-28-GST for *S. haematobium*[135] and Sm-14 for *S. mansoni*.[26,173] However, the correlates of protective immunity in humans are not well defined.[26,191] Vaccines related to several *S. japonicum* antigens also are being studied in animals, but efficacy is limited.[117,142,197] No vaccine is yet ready for clinical use.[16,67]

SUBSECTION 5 *ARTHROPODS*

CHAPTER 229

Arthropods

Jan E. Drutz

Arthropods comprise nearly three fourths of the world's animal species. Although some arthropods are capable of producing damage to agriculture and homes and others serve as reservoirs, hosts, and vectors of human and animal pathogens, the majority have no significant impact in causing human disease.[71] However, among the more significant diseases transmitted to humans by arthropods are Chagas disease, malaria, dengue, and bubonic plague. In the United States, ticks transmit more vector-borne diseases caused by bacteria, rickettsia, viruses, and protozoa than do any other species.

TICKS

Ticks, mites, spiders, and scorpions all belong to a class of arthropods known as Arachnida. Two of three families of ticks belonging to this class contain species capable of transmitting pathogens to humans. Ixodidae, the hard tick family, and Argasidae, the soft tick family, serve as both vectors and reservoirs for many rickettsiae (Table 229-1). By use of a fluorescent technique, these rickettsiae can be identified in the tick hemolymph.

Hard ticks are so named because of their scutum, a dorsal sclerotized shield. Owing to the limited scutum coverage of the female, she is more capable of becoming engorged with blood than is the male, a factor significant in the reproductive process. During feedings, these ticks remain attached to the host for hours or days at a time.[21,63] Three genera of Ixodidae are known to transmit disease to humans in the United States: *Amblyomma*, *Dermacentor*, and *Ixodes*.[62]

Soft ticks have no scutum and tend to live for long periods, often surviving for years without eating. Both the nymph form and the adult tick have a tendency to eat often but for brief periods often lasting less than 30 minutes.[21,63] Of the family Argasidae, only ticks of the genus *Ornithodoros* are known to transmit pathogens to humans in the United States.[62] Specifically, they are the vectors of tick-borne relapsing fever.

Local reaction from tick bites appears to be mediated by complement. The reaction from these bites may persist and subsequently develop into a so-called tick bite granuloma. Systemic reactions such as fever, chills, nausea, vomiting, abdominal pain, and headache can be associated with tick bites.

As noted, tick-borne diseases can result from infection with pathogens that include bacteria, rickettsia, viruses, and protozoa.[64] The major tick-borne diseases occurring in the United States include tick paralysis (discussed here), tularemia (see Chapter 132), tick-borne relapsing fever (Chapter 194), Lyme disease (Chapter 140), Colorado tick fever (Chapter 184), Rocky Mountain spotted fever (Chapter 194), ehrlichiosis (Chapter 194), and babesiosis (Chapter 218).

Tick-borne rickettsial diseases are clinically similar yet epidemiologically and etiologically distinct illnesses. In the United States, they include Rocky Mountain spotted fever, human monocytotropic (or monocytic) ehrlichiosis, human granulocytotropic (or granulocytic) anaplasmosis (formerly known as human granulocytotropic ehrlichiosis), *Ehrlichia ewingii* infection, and other emerging tick-borne rickettsial diseases.[13] Mediterranean spotted fever, a tick-borne disease caused by *Rickettsia conorii* (Chapter 194), is found almost exclusively in the Mediterranean area.

Within the past 10 years, five tick-borne diseases have been reported as occurring most often in the United States: Lyme disease, Rocky Mountain spotted fever, ehrlichiosis, anaplasmosis, and babesiosis. Lyme disease, babesiois, and anaplasmosis are all transmitted by the *Ixodes scapularis* tick. Among contributing factors possibly accounting for the prevalence of these diseases are an increase in the number of ticks, geographic spread, climatic change, improved physician awareness and reporting, and improved local and state surveillance.[24]

TABLE 229-1 **Human Infectious Diseases for Which Ticks are a Vector**

Disease	Agent
Relapsing fever	*Borrelia duttonii*
Q fever	*Coxiella burnetii*
Tularemia	*Francisella tularensis*
Queensland tick typhus	*Rickettsia australis*
Fièvre boutonneuse	*Rickettsia conorii*
Rocky Mountain spotted fever	*Rickettsia rickettsii*
Asian tick typhus	*Rickettsia sibirica*
Colorado tick fever	Arbovirus
Encephalitis	Arbovirus
Lyme disease	*Borrelia burgdorferi*
Human monocytic ehrlichiosis	*Ehrlichia chaffeensis*
Human granulocytic ehrlichiosis	*Ehrlichia* spp.
Babesiosis	*Babesia microti*

Tick Paralysis

Tick paralysis is a neurologic syndrome characterized primarily by an ascending flaccid paralysis. The etiologic agent is a potent neurotoxin produced by an attached, engorged tick.[32] A well-known disease of animals, it was reported to occur in humans in North America first in 1912.[67] Most cases have been reported in the Pacific Northwest and Rocky Mountain states, during spring and summer.[64] It occurs more frequently in children than in adults, especially in girls between 2 and 5 years of age. Patients present with paresthesias and leg weakness, but have no fever. Within 1 to 2 days, weakness in the legs ascends to the trunk musculature, resulting in an inability of the patient to sit or walk without assistance.[32]

Numerous genera of ticks are known to be associated with tick paralysis. In North America, *Dermacentor andersoni* (wood tick) and *Dermacentor variabilis* (dog tick) are the primary species responsible.[46] In Australia, the ticks implicated most commonly are *Ixodes holocyclus* and *Ixodes cornuatus*. Both male and female adults, as well as immature ticks, have been implicated as vectors for this disease.

Pathogenesis

Tick paralysis is thought to be caused by a neurotoxin (holocyclotoxin) produced in the tick's salivary glands.[44] It usually is released by gravid female ticks at the site of attachment, generally the scalp. The neurotoxin is a protein with temperature-dependent activity.[19] The exact mechanism and location of the toxin's action are not known but may include decreased entry of calcium into motor nerve terminals or interference with presynaptic excitation–secretion coupling, which leads to a reduction of acetylcholine release at the motor end plate.

Investigations in children with tick paralysis have implicated peripheral nerve dysfunction, attributable to somewhat site-specific diminished nerve conduction

velocities.[39,65] Compound muscle action potentials that are abnormally low or low-normal in amplitude when the patient has maximal neurologic deficits, generally are reversed rapidly once the tick is removed.[46] Swift and Ignacio[65] postulated that the major effect of the toxin is to prevent depolarization in the terminal portions of the motor neurons.

Clinical Manifestations

Onset of tick paralysis usually occurs 5 to 7 days after the female tick attaches to the skin. Until mating occurs with the male, engorgement of the female tick is relatively limited. Mating leads to rapid engorgement, fertilization of the eggs, and production of the neurotoxin. In turn, production of neurotoxin coincides with initial paralytic symptoms, and continual feeding accelerates production of toxin, accounting for rapid clinical deterioration. Once the female becomes engorged, she disengages from the skin to deposit her eggs.[32]

Ascending paralysis, along with hyporeflexia or areflexia, progresses to arms, and then to the bulbar structures involved in speech, swallowing, and facial expression.[32] Sensory function usually is spared, and the sensorium remains clear.[64] Alternatively, the disease can present as acute ataxia without muscle weakness.[47] Nystagmus, strabismus, and seizures may occur.[39] After tick removal, symptoms tend to resolve within several hours or days. Left untreated, tick paralysis can be fatal, with reported mortality rates of 10 to 12 percent.[59]

Routine laboratory tests are not helpful in establishing the diagnosis. The white blood cell count, urine analysis, cerebrospinal fluid, and erythrocyte sedimentation rate are usually normal.

Diagnosis

The diagnosis of tick paralysis can be established when the patient has the typical clinical picture and then improves rapidly after tick removal. A fine-toothed comb can aid in the detection of ticks attached to the scalp. The differential diagnosis of tick paralysis includes Guillain-Barré syndrome, botulism, poliomyelitis, myelitis, spinal cord neoplasm, syringomyelia, and porphyria. Botulism is characterized by slow, descending paralysis involving cranial nerves first, along with a usual extraocular palsy and large, poorly reactive pupils.[32]

The neurologic impairment caused by the *I. holocyclus* tick in Australia is more severe than that caused by *Dermacentor* spp. in North America. With exposure to *I. holocyclus* neurotoxin, the weakness and bulbar symptoms often intensify during the first 24 to 48 hours after tick removal. Clinical recovery is much slower than with *Dermacentor*-related paralysis. *I. holocyclus* antitoxin must be administered before removal of the ticks, and a longer observation period is required.[32]

Treatment

The earlier the tick is removed in the course of the illness, the more promptly the signs and symptoms will resolve. Forceps, not fingers, should be used to remove the tick. The tick's head should be gently but firmly grasped, and slow, reverse traction should be applied to remove all body parts. Recovery generally is complete within 1 to 5 days. In one reported case, weakness did not resolve for several months.[26] Intensive supportive care is required if the patient has cranial nerve dysfunction. Ineffective ventilation and ensuing respiratory failure require assisted ventilation.

MYIASIS

Myiasis is the invasion of a host's tissues by the larval stage (maggot) of nonbiting flies. Because of the immaturity of maggots, differentiating the various species is difficult. Myiasis can be classified according to the anatomic site of infestation (i.e., aural myiasis, ophthalmomyiasis, or cutaneous myiasis) or on the basis of the clinical syndrome (i.e., furuncular cutaneous myiasis, migratory cutaneous myiasis, or wound myiasis).[61] In the past, parasitic diseases were limited to their endemic areas. However, with the relative ease of worldwide travel, they are appearing with increasing frequency in the United States and other developed countries.[38]

Etiology

The true flies of the order *Diptera* undergo metamorphosis in four stages: egg, larva, pupa, and adult. To different degrees, some larvae of the suborder Cyclorrhapha have adapted to a parasitic relationship with humans. Some are classified as obligate, facultative, or accidental parasites in humans. In each case, the larval stage of the fly is able to invade the tissues of the host and progress in the stages of metamorphosis.

Epidemiology

The occurrence of human myiasis has been linked to humid and warm climates that favor the breeding of flies. Epizootics in livestock, marginal housing, poor disposal of refuse, and under-nutrition also are important factors in the development of human myiasis.[50] In the United States, myiasis has been reported both from flies native to North America and from the larvae of flies acquired during foreign travel. More than 50 species of flies have been reported to cause human myiasis.

Pathogenesis

The pathogenesis of human myiasis differs with the degree of parasitic adaptation by each fly. *Dermatobia hominis* (the human botfly) uses a bloodsucking insect as a vector to deposit its eggs on a warm-blooded host. The larvae emerge from the eggs and then penetrate the host's skin, frequently using the puncture site of the carrier insect. The larvae develop within the dermal layer of skin, which leads to a boil-like swelling. During this period, the human host develops clinical symptoms. *D. hominis* and *Cochliomyia hominivorax*, the primary screwworm, are examples causing obligate myiasis.[50] *C. hominivorax* can be responsible for aural or nasal myiasis.

The genus *Sarcophaga* (flesh flies) is capable of causing facultative myiasis. The adult fly is attracted to wounds or ulcers containing purulent and necrotic material. The adult fly deposits eggs in the open wound, where the larvae hatch.

Maggots seldom are found in the human intestinal or urinary tract.[61] Accidental myiasis can occur when humans ingest eggs or larvae and the larvae remain in the intestinal tract. Genitourinary myiasis is thought to occur by the deposition of eggs around the external urethral orifice. The larvae then may migrate into and up the urethra. Such situations should be called *pseudomyias*,[76] because the maggots are not living parasitically.

Clinical Manifestations

The lesions of cutaneous myiasis generally are located over the exposed area of the body. Early in the course of cutaneous myiasis, pruritus is the predominant symptom. As the larvae grow after the first week of infestation, a serous exudate may drain from the penetrating site. At this point, pain and pruritus are prominent symptoms and the lesion appears as a small furuncle (furuncular myiasis).[27] Tissue destruction by the larvae may continue, and secondary bacterial infection can occur. *Staphylococcus aureus*, group A streptococci, and gram-negative organisms have been isolated from infected cutaneous myiasis wounds.

Abdominal pain, diarrhea, and anal bleeding are the symptoms of intestinal myiasis, which is self-limited and may last 2 to 6 weeks. Larvae within the genitourinary tract may lead to proteinuria, dysuria, hematuria, and pyuria. Nasal myiasis can extend into bone, sinus cavities, and even the meninges.[4] Aural myiasis has been described in a child without underlying disease.[20] Ophthalmomyiasis is characterized by an acute catarrhal conjunctivitis.[27] Penetration into the brain has been associated with intracerebral hematomas.[45]

Diagnosis

A careful history of travel, occupation, and exposure is necessary to establish the diagnosis when the physician is confronted with unusual skin lesions that are pruritic and have not resolved with usual local care.[37,42] Myiasis is confirmed if larvae are demonstrated within the wound. A parasitologist or entomologist may be able to identify the species of larvae responsible.

Treatment

The removal of the larvae is necessary in any of the forms of myiasis. Endoscopic removal of nasal infestation is recommended. Surgical intervention may be required to expose the larvae in the wound. Forceps are used to pick out the larvae; the application of 5 percent chloroform in olive oil may facilitate removal. Occlusive coverings of the wound opening are helpful in extruding *Dermatobia* larvae because this tends to diminish the oxygen supply for the larvae. A thick layer of petrolatum jelly (Vaseline) effectively interrupts the airflow.[51] Local or systemic antibiotics may be required if secondary bacterial infection is present.

The prevention of human myiasis requires good wound care, adequate personal hygiene, screening to protect against flies, and the prevention of myiasis in domestic animals.

Mites

As mentioned earlier, mites belong to the same class of arthropods (Arachnida) as ticks, spiders, and scorpions. They, too, can be vectors for infectious agents. The house mite, *Liponyssoides sanguineus*, is the vector for rickettsialpox (Chapter 194) agent. Chiggers, which are larvae of mites (family Trombiculidae), transmit to humans the agent responsible for scrub typhus, *Rickettsia tsutsugamushi* (Chapter 194).

Some mites transmit no specific disease but can cause an annoying pruritic rash. In 2004, the microscopic itch mite *(Pyemotes herfsi)* was identified as a likely cause of an intensely pruritic skin reaction in individuals living in several Midwestern states, as well as Texas and Oklahoma. Skin lesions were papular and erythematous and occurred primarily on the face, neck, and limbs.[12]

Scabies, an extremely pruritic skin infestation, has been known for more than 2500 years. The etiologic agent for this condition, *Sarcoptes scabiei* var. hominis, is an obligate human parasite that burrows into the epidermis, no deeper than the stratum granulosum.[16] Scabies appears to have an increased incidence in 15-year cycles.[60] and is transmitted person to person through direct and usually prolonged contact.

Pathogenesis

Mites of all developmental stages tunnel into the stratum corneum and deposit feces (scybala) behind them. Characteristically, the gravid female lays eggs in the tunnels.[36] Clothing and bed linens are thought to be less important in the transmission of the *Sarcoptes* mite. Because scabies is transmitted by skin-to-skin contact, sexual transmission occurs commonly, as does nonsexual spread in family settings.[16] Epidemic outbreaks of scabies have been reported in hospitals and other institutions where people were living closely together and especially where poor sanitation predominated.[6]

Hypersensitivity of both immediate and delayed types has been implicated in the development of lesions other than burrows.[16] Papulovesicular scabies is characterized by perivascular lymphohistiocytic infiltrates with eosinophils. The papillary dermis is edematous. The histologic appearance of nodular scabies is one of a dense, superficial, and deep perivascular lymphohistiocytic infiltrate with many plasma cells and eosinophils. Various vascular changes also may be apparent.

Clinical Manifestations

Scabies is characterized by moderate to severe pruritus that starts several weeks to months after infestation, at which time the host has become hypersensitive to the mite or its products. Itching, most evident at night, is the primary symptom of infection. A papular or vesicular eruption with pustules and linear burrows occurs and

classically involves the webs between the fingers, flexures of the arms, axillae, and genital regions of adults. In infants and children, scabetic lesions more typically occur on the palms, soles, head, and neck in the form of vesicles, pustules, or nodules. In this age group, scabies often is not suspected because of the atypical skin lesions that result from vigorous scratching and secondary infection.[41]

Acute glomerulonephritis may be associated with pyoderma in scabies. A careful history may reveal that other family members or child caretakers have pruritus and skin lesions consistent with scabies. Examination of the skin of family members for signs of scabies frequently is helpful. Crusted scabies, previously known as Norwegian scabies, occurs in immunocompromised patients, especially those on immunosuppressive medications or those with human immunodeficiency virus (HIV) or human T-lymphotropic virus type 1 infection.[33] In this condition, mite replication is uncontrolled by the host's immune system.[22,33] It is a psoriasiform dermatitis, frequently associated with a generalized or localized nonspecific hyperkeratosis.[28,33]

Diagnosis

Definitive diagnosis can be made by microscopic identification of the mites, eggs, or mite feces.[40] To obtain this material, skin scrapings should be taken from papules or the end of a burrow or from underneath the surface of fingernails. In some cases, a variety of biopsy techniques can be useful.[9] The diagnosis should be considered when the physician is faced with an unusual papular or bullous rash. The differential diagnosis of scabies in children includes impetigo, atopic eczema, seborrheic or contact dermatitis, psoriasis, histiocytosis, and chickenpox.[40,41]

Treatment

The management of scabies involves the application of a topical scabicide to all areas of skin, including the face and scalp, with subsequent removal in 8 to 24 hours, depending on the product applied. An effective scabicide used in the past was gamma-hexachlorocyclohexane (lindane). It is no longer recommended for use in children, because of concerns regarding neurotoxicity.[22,48] Currently, effective topical scabicides licensed in the United States include 5 percent permethrin and 10 percent crotamiton. Although 5 percent malathion lotion is approved in the United States for treatment of head lice (see later discussion of head lice treatment), it has not received U.S. Food and Drug Administration (FDA) approval to be used as a scabicide.[36]

The agent of choice for infants and young children is 5 percent permethrin topical cream, applied in the evening to the entire head, neck, and body of the infant and left on overnight.[41] It is indicated and safe for use in newborns and young children, as well as pregnant and lactating women.[36] A second application generally is recommended 1 to 2 weeks after the first dose.[22,36] All family members should be treated simultaneously.[55] Antibiotics may be necessary if secondary bacterial infection is present.

The Centers for Disease Control and Prevention (CDC) has recommended the off-label use of oral ivermectin 200 μg/kg/dose given with food for the treatment of scabies, though the FDA has yet to grant such approval.[22] Ivermectin is considered to be highly efficacious as an oral therapy for scabies in a single dose for otherwise healthy or HIV-infected adults.[52] Some have recommended two doses, with the second dose given 1 to 2 weeks after the first dose.[22] It works against several different parasites by interrupting gamma-aminobutyric acid–induced neurotransmission.[16] The CDC recommends not using ivermectin in pregnant or lactating women and states that safety has not been determined in children who weigh less than 15 kg.

Articles of clothing and bed linens should be machine washed in hot water at 60° C (140° F). Insecticidal powder or aerosol should be reserved for materials that cannot be washed.[16] Pruritus often persists for some time after successful treatment with a scabicide and may be relieved by an oral antihistamine or mild to moderate topical steroids.[9,55] In hospitalized patients, contact isolation is recommended to lessen the potential for nosocomial transmission.

PEDICULOSIS

Arthropods of the order Anoplura (sucking lice) are important as vectors of rickettsial or spirochetal illnesses. The body louse, *Pediculus humanus humanus*, is the vector for epidemic typhus *(Rickettsia prowazekii)*, trench fever *(Bartonella quintana)*, and louse-borne relapsing fever *(Borrelia recurrentis)*. The body louse, head louse *(Pediculus humanus capitis)*, and crab louse *(Phthirus pubis)* all are capable of achieving human infestation. Pediculosis has been a problem for humans for more than 10,000 years.[16]

Pathogenesis

Head lice are the most common type of louse, affecting more than 100 million people worldwide each year.[17] Tiny, they measure no more than 1 to 4 mm in length. They have six legs, each with powerful claws allowing firm attachment. Mouth parts consist of stylets (retracted when not in use) modified for piercing and sucking. When they are not feeding, lice are translucent, with grayish-white bodies, but when engorged with blood, they become red. Each female is capable of laying as many as 300 eggs (nits) in a brief lifetime of 1 to 3 months. These eggs are less than 1 mm in diameter and hatch in 6 to 10 days, giving rise to nymphs. During a period of 10 days, the nymphs become adults. School children of all socioeconomic groups are affected, with head-to-head contact being the most common means of transmission.

Clinical Manifestations

Children or adults with head lice usually have white or opalescent nits attached to individual strands of hair. The lice themselves firmly adhere to the base of the hair shaft,

millimeters from the scalp. Once a louse pierces the skin, a poisonous salivary secretion is exuded, resulting in pruritic dermatitis. Itching is the primary symptom in acute cases.

Body lice occur when socioeconomic conditions are poor. Infestation occurs when people fail or are unable to wash their clothes regularly, such as those living in refugee camps. Intense itching is a major problem, with noticeable excoriations and occasional secondary infections.

Pubic lice are transmitted primarily through sexual contact, although not exclusively so. In children, pubic lice generally occur from nonsexually transmitted contact with an infected parent. Again, itching is a major presenting symptom. Pubic lice may become attached to other hairy areas of the body, such as the axillae of adolescents, the eyelashes of children, and the scalp hair of any age group.[16]

As mentioned, body lice can function as vectors for the transmission of several diseases. One of these is trench fever, caused by *B. quintana*. Although some patients may have no symptoms, others may have fever, myalgias, headache, meningoencephalitis, transient maculopapular rashes, or chronic adenopathies. A second potentially transmitted disease is epidemic typhus, caused by *R. prowazekii.* Signs or symptoms of this infection may include fever, pruritic rash, headache, and confusion. Relapsing fever caused by *B.* recurrentis is the third disease known to be transmitted by the body louse.[16]

Diagnosis

Head, body, and pubic lice are visibly recognizable. The nits of head lice are attached firmly to hair shafts and are distinguished readily from dandruff flakes, lint, and other debris, which can be easily removed from the hair. Viable nits, located close to the scalp, are oval and grayish-white to yellow-white. Empty nonviable nits, attached at some distance from the scalp, are almost completely clear. Although difficult to see with the naked eye, nits visibly fluoresce yellow-green under Wood's lamp. Polymerase chain reaction (PCR) helps identify host DNA from lice through their blood meal, providing valuable information for rape, homicide, and child abuse cases.[49]

The body louse has been demonstrated as the true vector of trench fever by using PCR to detect within them the *B. quintana* DNA from infected patients.[8] Detection of rickettsial DNA in body lice has confirmed the presence of human typhus.

Treatment

Head Lice

Numerous forms of treatment for the eradication of head lice have been used. Over the course of time, resistance developed to several of these forms of therapy. Gamma-hexachlorocyclohexane (lindane) shampoo was used almost exclusively until the early 1970s. Because of concern about potential neurotoxic effects for the patient, it no longer is recommended as a first-line medication for children.[48]

A systematic review (1995) concluded that sufficient evidence existed only for the use of a pyrethroid insecticide, 1 percent permethrin cream rinse.[17,68] This biodegradable and generally very safe product remains the recommended first-line therapy. It should be applied to wet hair and left in place for about 10 minutes before rinsing. Because of variable reports of head lice resistance to 1 percent permethrin, the current recommendation is two treatment applications 7 to 14 days apart, or even three treatments at 0, 7, and 15 days, based on the life cycle of head lice.[5] Some success has been reported with use of a 5 percent permethrin preparation and wearing a shower cap overnight.[57] To remove the firmly adherent nits, a fine-toothed stainless steel comb (LiceMeister) has been recommended.

Malathion lotion 0.5 percent, an organophosphate, has been an excellent alternative to the use of permethrin in areas where head lice-resistance has occurred. When applied to the hair and left in place for 8 to 12 hours, it provides residual protection. Caution should be taken because it is potentially flammable. Those treated should not be exposed to open flames or electric heat sources, including hair dryers and electric curlers.[1,5]

Cases of resistance to the malathion-containing formulation have been reported in Europe, but that product is different from the one licensed in the United States. The latter contains additional synergistic agents, including 78 percent isopropanol. Because it is hydrolyzed and detoxified by plasma carboxylesterases much more rapidly in mammals than in insects, it is considered safe. Although it is contraindicated for use in infants, the American Academy of Pediatrics considers it be safe for use in children 2 years of age and older.[1,5]

Ivermectin has been used when other medications have failed. A dose of 200 μg/kg given on days 1 and 8 appears to be effective. Concern exists when the drug is used in patients weighing less than 15 kg or those who are pregnant or breast-feeding.[10]

As a result of reports of difficult-to-treat head lice infestation, authors in one cluster-randomized, double-blind, double-dummy, controlled trial compared ivermectin 400 μg/kg to the application of 0.5 percent malathion lotion, each given on days 1 and 8. Ivermectin was reported to have superior efficacy. However, the malathion product was not the one licensed in the United States.[17]

In addition to malathion, two other topical pediculcides have received FDA approval for pediatric use. Labeled for use in children 6 months or older, benzyl alcohol should be applied to dry hair for at least 10 minutes. If live lice persist, a second application should be administered 7 days later. For children 4 years of age or older, spinosad should be applied in the same way as benzyl alcohol.

There have been other recommended approaches to the treatment of head lice, all with somewhat limited success. A short course of oral trimethoprim-sulfamethoxazole had been recommended in the past with the intent of destroying essential lice gut bacteria,

responsible for the production of vitamin B, essential for continued life. A nonchemical approach to treatment has been the application of a topical lotion (Cetaphil Skin Cleanser) to the hair, with subsequent use of a blow dryer to "shrinkwrap" and ultimately suffocate lice.[54] Although this approach may result in significant success, the original study was not sufficiently rigorous to prove its effectiveness.

The use of a high-volume, hot-air blow dryer alone has been reported to have killed 94 to 98 percent of lice eggs and 76 to 80 percent of hatched lice.[35] When examined 1 week later, virtually all of the patients were completely cured. Although promising, this approach necessitates further testing by independent investigators. If proven to be efficacious, it could potentially eliminate the use of chemicals, to which some lice have become resistant.

Body Lice

A general recommendation has been thorough washing of the body with soap and water followed by the application of a pyrethrin or pyrethroid or malathion for 8 to 24 hours. Again, caution should be taken in the use of these preparations in children. Decontamination of clothing and bed linens is essential by either washing them in hot soapy water at a temperature of 54° C (130° F) for 10 minutes or placing them in a hot clothes dryer for 20 minutes.

Pubic Lice

Treatment should be similar to that used for managing head lice. Clothes and bed linens should be decontaminated. In the case of children, parents also should be treated; and in the case of adolescents, sexual partners require treatment.

BED BUGS

Numerous recent reports have documented the reemergence of bed bugs *(Cimex lectularius)* as a cause of pruritic, erythematous papules.[14,66] Although they are known to harbor pathogens (e.g., plague and hepatitis B), bed bugs are considered incapable of transmitting those diseases to humans[43,69] and therefore are not thought to pose a medical threat. Secondary skin infections, however, can develop as a result of persistent scratching, and allergic reactions are a possibility.

The upsurge in bed bug infestation has been attributed to various factors, including increased international travel and transport, exchange of secondhand furniture, insecticide resistance, and changes in insecticide use.[23] The primary result of contending with these annoying insects has been both social and psychological. Hotels, department stores, apartment buildings, and individual home owners have encountered a significant economic loss in their efforts to eliminate these pests.

Pathogenesis and Clinical Manifestations

Bed bugs tend to be nocturnally active and are attracted to humans by arm body temperature and the exhalation of carbon dioxide. Most can be found within 5 feet of the bed. Survival depends on blood extracted from their respective hosts, which is achieved by piercing the skin with their beadlike proboscis containing a set of two hollow tubes. Online videos are available for viewing actual bed bug feeding.[25] Through one of these tubes, they inject saliva containing both anticoagulants and anesthetics; through the other one, blood is withdrawn.[66] Although they can live for up to 18 months without feeding, bedbugs typically seek blood every 5 to 10 days.

Feeding time generally takes place in the early morning hours, when the host is most calm and least likely to sense the presence of a crawling insect. Because bed bugs are opportunistic feeders, shift workers, who sleep during the day time, also are vulnerable.

Total feeding time can range from as short as 5 minutes to as long as 30 minutes, after which the insect abandons the skin surface and seeks seclusion among bed sheets, blankets, mattresses, floorboard cracks, or other crevices.[66] The host generally does not experience itching or skin irritation until several minutes or hours after the insect has fed. In some cases, no skin reaction occurs at all.

Diagnosis

Suspicion for the possible presence of bed bugs occurs when the host awakens with itching and visible bites not present before going to sleep. Clues to the presence of bed bugs include discrete reddish-brown bloodstains on sheets and mattresses, as well as flecks of excrement at the portals of hiding places.[64] Confirmation requires finding and identifying these bugs. Current approaches to early detection include the use of various lures or traps and training dogs to pick up the scent of certain bed bug pheromones.[23]

Treatment

Treatment of bites is relatively conservative, directed toward symptomatic relief of itching, irritation, and secondary infection. Antipruritic medication, either topical or oral preparations, may be considered. First-generation antihistamines can help alleviate the itching but may be sedating. Topical corticosteroids can help reduce the erythema and itching. Oral antibiotics alone are sufficient to treat secondary bacterial skin infections.

Eradication

Insecticides containing pyrethroids are used widely as a control measure; however, pyrethroid-resistant bed bug populations have been found in some states. Nonchemical methods to effectively control bed bugs include heating infested rooms to 48°C (118° F) for 1 hour or cooling rooms to –16° C (3° F) for 1 hour; encasing mattresses and box springs with bed bug–excluding covers

and vacuuming, steaming, laundering, and disposing of infested items. Any effective control measure for bed bugs requires support from all residents in affected buildings and ongoing monitoring for infestation from other housing units. In addition, multiple inspections and treatments frequently are needed.

In a relatively recent report, a total of 111 illnesses, representing seven different states, were associated with bed bug–related insecticide use. The majority of the illnesses were of low severity (81%). One fatality was confirmed. The most common factors contributing to illness were excessive insecticide applications, failure to wash or change pesticide-treated bedding, and inadequate notification of pesticide application.[15] To rid the living environment of bed bugs, a professional exterminator should be consulted.

SPIDERS

Of the thousands of species in the United States, only a few pose a threat to humans. Species of the genus *Loxosceles* are the spiders predominantly responsible for necrotic arachnidism in the United States. The two most common species are the black widow spider *(Loxosceles mactans)* and the brown recluse spider *(Loxosceles reclusa)*. Both prefer dark, undisturbed habitats, such as outdoor lavatories, woodpiles, underside of stones, or dark corners of garages and attics. The black widow has a characteristic red hourglass shape on its ventral surface. The brown recluse has a violin-shaped marking over its dorsal surface. In the Pacific Northwest area of the United States, the hobo spider *(Tegenaria agrestis)* produces an envenomation similar to that of the brown recluse spider.[11]

Pathogenesis

Venom from the black widow contains a neurotoxin (α-lactotoxin), not a tissue toxin. The main effect is at the presynaptic membrane of the neuromuscular junction. Venom from the brown recluse spider contains sphingomyelinase D, a phospholipase that induces dermal necrosis and also causes systemic effects through its interaction with red blood cells, platelets, and endothelium.[58] The necrosis caused by the venom depends on neutrophils, but the neutrophils are not activated by the venom itself. Rather, the venom is a potent stimulus for the inflammatory response of endothelial cells, which in turn activates the polymorphonuclear neutrophils to cause tissue destruction.[53]

Clinical Manifestations

The bite of the black widow spider generally is painless, but a target lesion may develop. Within 30 to 120 minutes, some patients complain of regional lymph node tenderness.[75] The primary symptom that follows the bite is muscle cramping, generally involving the abdomen, chest, or back, depending on the location of the bite. Autonomic symptoms, including profuse sweating, nausea, vomiting, and tachycardia, may occur.[58] Hypertension can be a significant problem. The degree of systemic symptoms depends on the amount of venom injected and the number of bites. Severe cases may progress to internal hemorrhage, paralysis, and, rarely, even death.

The brown recluse spider bite may produce a mild or sharp stinging sensation. After several hours, the pain intensifies and itching occurs.[2] Eventually, a blister with surrounding erythema forms at the site. In the course of time, the lesion becomes larger, and central necrosis develops. Systemic signs developing in the first 24 to 48 hours may include headache, fever, nausea, vomiting, and joint pain. Disseminated intravascular coagulation, multiorgan failure, and death have been reported in children.[34,72]

Like that of the brown recluse spider, the bite of the hobo spider may result in a central necrotic area. The most common systemic symptom is a severe headache. Protracted systemic effects, including aplastic anemia, intractable vomiting, and profuse secretory diarrhea, are rare occurrences but may be associated with death.[70]

Treatment

For the patient who has been bitten by a black widow spider, analgesia is the mainstay of care.[58] An antivenin is available, but only for the most severe cases of envenomation, unresponsive to other measures.[7]

For bites of brown recluse spiders, numerous treatments have been used, including hyperbaric oxygen therapy, early excision, antibiotics, dapsone, and corticosteroids. Careful supportive care, including monitoring of electrolytes and renal function, is required if symptoms are severe.[58] Systemic corticosteroid therapy may be of some benefit if the patient has considerable symptoms. Dapsone, an inhibitor of neutrophil function, appears to decrease the development of wound complications and subsequent need for surgical excision.[56]

SCORPIONS

Scorpions, like ticks, mites, and spiders, belong to the Arachnida class of arthropods.[30] The striped bark scorpion *(Centruroides vittatus)* is the most common type of scorpion found in the United States.[29] The most dangerous and perhaps the most lethal scorpion in this country is *Centruroides exilicauda* (former species name, *sculpturatus*), occasionally referred to as the bark scorpion.[31,58] It is indigenous to the desert Southwest, particularly Arizona. Depending on the species, scorpions tend to reside in cracks and crevices, in cupboards and closets, or under loose tree bark. They inject their venom when disturbed or threatened.

Pathogenesis and Clinical Manifestations

C. vittatus produces a neurotoxic venom stored in poison glands in the tip of the tail. The venom of these scorpions is deadly to insect prey and produces a painful sting for humans. For those allergic to the sting, an anaphylactic reaction may occur.[29] The venom from the *Vaejovis*

carolinianus (plain eastern stripeless scorpion) is considered to be mild, similar to that of a honeybee sting. Anecdotal reports indicate that on occasion, a severe reaction may occur.[30] The *C. exilicauda* scorpion produces a neurotoxic venom that can lead to cardiac failure, respiratory paralysis, agitation, paresthesias, hypersalivation, hypertension, and gastrointestinal symptoms. Although tachycardia and hypertension are frequent reactions, opposite effects are a possibility when the venom activates the parasympathetic nervous system.[56] The absence of local tissue reaction is helpful in distinguishing *C. exilicauda* stings from those of other scorpions found in Arizona.[31] Children and elderly adults are most at risk as a result of envenomation from *C. exilicauda*.[29]

Treatment

Most scorpion stings necessitate only nonprescription analgesic medication. For the management of *C. exilicauda* envenomation, atropine can be used to control hypersalivation, although it could be contraindicated when the sting has been produced by scorpions foreign to the United States. In some of those cases, the use of atropine can exacerbate an adrenergic toxicity reaction created by the sting of the scorpion. Treatment of *C. exilicauda* envenomation with an antivenin (available in Arizona only; not approved by the FDA) has been reported to provide relief from the neurotoxic effects. It has the unfortunate potential of causing both immediate and delayed hypersensitivity reactions.[31,58]

MURINE TYPHUS

Also known as endemic typhus fever, murine typhus is a worldwide flea-borne infection of humans. It is caused by *Rickettsial felis* and *Rickettsial typhi*.. The disease most commonly occurs among people in contact with rats or areas where rats live, but also occurs among people who live near or have contact with other small mammals (e.g., opossums and cats). Cases reported in the United States are usually confined to suburban areas of Texas and Southern California, as well as several Hawaii islands. The cat flea *Ctenocephalides felis* is considered to be the primary vector.[18] The disease is often difficult to diagnose, because of its nonspecific clinical presentation. Clinicians are led to believe that patients have other, more commonly seen vector-borne infections, such as dengue fever, ehrlichiosis, West Nile virus, and Rocky Mountain spotted fever, or non–vector-borne infections (e.g., bacterial or viral meningitis disease, Kawasaki disease, or secondary syphilis).[18]

Pathogenesis and Clinical Manifestations

Like other rickettsiae, *R. typhi* is a small (0.4 to 1.3 mm) gram-negative obligate intracellular bacterium depending on hematophagous arthropods (e.g., fleas and ticks) and mammals to maintain its life cycle. *R. typhi* multiplies in the epithelial cells of the flea midgut and subsequently are shed into the feces, which in turn are deposited on the host skin surface while the flea is feeding.[18] Humans and other mammals acquire the bacteria when the flea bites or feces are inoculated into the bite site.[3] *R. felis* has been identified as the cause of typhus-like illness in the United States (Texas), Mexico, France, and Brazil. Molecular studies have found that *R. felis* and *R. typhi* are indistinguishable serologically and require separate identification using PCR analysis.[18]

Following an incubation period of 1 to 2 weeks, the most common symptoms include 3 to 7 days of fever, headache, exanthema, and arthralgia. The exanthema can be variable from patient to patient. It can be macular or maculopapular and nonpruitic, beginning on the trunk, eventually spreading to the arms and legs, but sparing the palms and soles. It appears about 7 days after the onset of fever and remains unchanged for a period of 1 to 4 days.[18]

The mortality rate for murine typhus is low with use of appropriate antibiotics (1%) and about 4 percent without the use of antibiotics. In most cases, it will present as an acute, self-limited illness without complications. However, serious complications have been associated with acute infection, including endocarditis, splenic rupture, and aseptic meningitis.[18]

Diagnosis

Most rickettsial infections are diagnosed using serologic methods such as IFA, often considered to be the most ideal test. Unfortunately, serologic studies are rarely diagnostic when blood specimens are collected at the onset of symptoms. A convalescent-phase specimen, yielding a fourfold increase in titer between the acute- and convalescent phase samples, is usually required to confirm the diagnosis.[18,74]

Other available serologic assays include the indirect immunoperoxidase assay, latex agglutination, line blot, and Western immunoblot. Isolation of rickettsiae from blood cultures is rarely successful and usually necessitates the expertise of a specialized research laboratory. Diagnosis has been made by PCR with the use of peripheral blood, buffy coat, and plasma specimens and occasionally with fresh-frozen or paraffin-imbedded tissue specimens or with arthropod vectors acquired during ecologic surveillance (i.e., cat fleas).[18,74]

Treatment

Antimicrobial testing is not routinely performed on rickettsiae. As with other rickettsial diseases, the preferred antibiotic is a tetracycline, particularly doxycycline for children 9 years of age and older. The course of treatment is usually a week or less, limiting the risk for dental staining.[13,73]

SECTION **XXIII**

GLOBAL HEALTH

CHAPTER 230

Global Health

Holly Corwin • Gail J. Harrison

The keys to success as a global health professional are compassion, competence, critical thinking, and creative adaptability.
Chunhuei Chi

This chapter on Global Health will provide an introduction to the definition, evolution, disciplinary perspectives, interventions, and contemporary challenges associated with global health. For information on specific health conditions and infectious diseases of global concern, such as human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS), malaria, tuberculosis, parasites, or specific circumstances, such as international adoptions, the reader is referred to the individual chapters for each of these entities.

DEFINITION OF GLOBAL HEALTH

The term *global health* is widely used and very popular among academic institutions, humanitarian and government agencies, nongovernment organizations (NGOs), and nonprofit organizations around the world.[2,3] Global health is increasingly mentioned as an area of public health and medical professional interest, as well as a philanthropic goal, but is rarely defined by a definition agreed on by even the most influential health organizations.[2,3,20] Many organizations and institutions have used the term *global health* as a state of being or condition, as a goal, or as a field of study that relates to education, research, and practice. Uniformity of definition is desirable, because it sets the foundation for collaborative efforts of global purpose, clear objectives for action, and reliable instruments for measuring achievements. Fragments of public health and international health definitions, which evolved from hygiene and tropical medicine, have been used to assemble a concept of global health that is becoming universally accepted.[4-6] Global health often overlaps in the fundamental purpose and initiatives of both public and international health and can be seen as evolving from both disciplines. An understanding of the history and evolution of definitions of health, public health, and international health is helpful in understanding the overall objective of global health.[20]

The World Health Organization (WHO), one of the leading authorities for health, has defined health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity."[7] This definition was the basis from which the WHO worked their evolving and emerging projects toward the goals to improve the overall health of the world. This definition is broad and all-inclusive and includes the larger picture of overall health for one person, or a whole community, and covers not only the administration of medical attention, but also prevention of disease through public health, policy, mental well-being, research, and many more factors influential in health.

The current public health concepts emerged in mid-19th–century Europe and the United States. During this time, medical advances in the cause, management, and prevention of infectious diseases and the growth of social reform movements helped establish the discipline of public health with four main concepts: (1) decision making based on data and evidence gathered through vital statistics, surveillance, outbreak investigations, and scientific method; (2) focus on populations or groups rather than individuals; (3) action rooted in social justice and equity; and (4) prevention of disease rather than treatment or cure of established disease. In 1988, the Institute of Medicine reconfirmed public health as a preventive discipline that employs a community approach and involves multiple partners working toward a common good of public health. The American Public Health Association (APHA) defines public health in contemporary terms as "the practice of preventing disease and promoting good health within groups of people, from small communities to entire countries" including the well-being of the population of a specific country or community within a country.[4] Public health practice emerged from the works of many pioneering scientists and physicians and the early discoveries about quarantine, sanitation, and housing; public knowledge on sexually transmitted infections and diseases; and vaccinations. Eventually, the practice of public health evolved from early efforts of individuals to organized efforts among societies and nations.

The field of international health was further developed from public health, hygiene, and tropical medicine disciplines, as medical missionaries, scientists, and other humanitarians traveled and shared their discoveries and new ideas. The specific focus of international health and international medicine currently lies in the differences among countries, peoples, and regions. International health applies the well-established public health principles of industrialized countries to assist the health

TABLE 230-1 **Comparison of Global, International, and Public Health**

Comparison Factors	Global Health	International Health	Public Health
Geographic reach	Focuses on issues that directly or indirectly affect health but that can transcend national boundaries.	Focuses on health issues of countries other than one's own, especially those of low and middle income.	Focuses on issues that affect the health of the population of a particular community or country.
Level of cooperation	Development and implementation of solutions often requires global cooperation.	Development and implementation of solutions usually requires binational cooperation.	Development and implementation of solutions does not usually require global cooperation.
Individual or populations	Embraces both prevention in population and clinical care of individuals.	Embraces both prevention in populations and clinical care of individual.	Mainly focused on prevention programs for populations.
Access to health	Health equity among nations and for all people is a major objective.	Seeks to help people of other nations.	Health equity within a nation or community is a major objective.
Range of disciplines	Highly interdisciplinary and multidisciplinary within and beyond health sciences.	Embraces a few disciplines but has not emphasized multidisciplinary.	Encourages multidisciplinary approaches, particularly within health sciences and with social sciences.

From Koplan JP, Bond TC, Merson MH, et al. Towards a common definition of global health. *Lancet* 2009;373:1993-1995.

problems and challenges of low-income populations in developing countries, through foreign aid activities and missionary work (Table 230-1). It often includes "diseases of the developing world" and "health work abroad," with a focus on infectious and tropical diseases, water and sanitation, malnutrition, and maternal–child health.[4-6] Previously, *international health* and *global health* were considered interchangeable terms, whereas now most experts recognize them as distinct disciplines and practices.[20]

Global health transcends the individual nations and borders and emphasizes worldwide improvement of health, reduction of disparities, and protection against threats to health of the people of all nations (see Table 230-1). Global health focuses on the similarities throughout the world, and the issues that cross nations.[20] It blurs the borders to create a sense of unity and understanding of how people, cultures, and the environment interact and affect each other. It emphasizes both the individual and the population and strives for equity among people of all nations. It also is highly interdisciplinary and multidisciplinary in its approach to problem solving and strives to provide creative and sustainable solutions for resource management in resource-poor regions (see Table 230-1).

Current global health issues involve not only the direct health impact, but also other disciplinary perspectives that indirectly influence health, such as climate change and natural disasters, economics, politics, conflict, war, migration, food crisis, energy crisis, and neglected diseases.[1] The political perspective of global health emphasizes the influences of war and economy on the health of the world. The educational and research perspectives of global health are evident when taught as curriculum in both medical and sociologic disciplines and are an educational goal of many institutions of higher learning. The epidemiologic perspective of global health identifies and follows trends of major global health threats and partners with the medical perspective to describe the pathologic factors, clinical manifestations, diagnosis, treatment, and prevention of these diseases. From an economic perspective, global health emphasizes cost-effectiveness and cost-benefit approaches for population health and includes the measurement of health burden, including life expectancy; adult, maternal, infant, and child mortality; disability; and quality of life.[11-13] Many experts also view global health from the ethical and societal perspective and include educational disparities, reproductive health, violence against women and children, and child labor and hawking laws as a global health concern.

HISTORY AND EVOLUTION OF GLOBAL HEALTH

The beginnings of the contemporary concepts surrounding global health evolved from European colonization and colonial enterprises. Colonialism affected the public health of the world at the time, through the introduction and rapid spread of non-native diseases, such as measles, smallpox, and malaria to previous nonimmune indigenous people in Saint Domingue, Haiti and the Americas. In addition, the extraction of wealth prevented the indigenous people from exiting the cycle of poverty and disease. Furthermore, colonization of Africa, India, and the Americas by British and other Europeans created urban centers and crowding that bred infectious diseases such as cholera, tuberculosis, and smallpox and fueled the HIV/AIDS epidemic. In contemporary terms, international spread of disease, such as influenza pandemics, through international travel, or, potentially, by bioterrorism is a global health concern.

Medicine underwent a dramatic change in the late 19th century with the discovery of the germ theory of

disease and the awareness of it in the public health consciousness.[4] Proponents of the germ theory included Louis Pasteur, the father of the germ theory and early vaccinology, Robert Koch, father of Koch's postulates to establish a list of criteria to determine the cause of a disease, and John Snow, the father of modern epidemiology, who discovered the transmissibility of cholera and its prevention. In 1902, a model international collaboration to fight yellow fever created the Pan American Health Organization. After World War I, the League of Nations Health Committee changed its focus on infectious diseases to include nutrition and maternal and infant health. In 1947, the WHO was created by the United Nations to serve as a single global entity charged with fostering collaboration among member nations to work toward the new definition of health as a state of well-being and not merely the absence of disease. During this time the social determinants of health began to coexist with the advent of health care delivery and treatment of infections and other diseases.

This history of global health also has included disease eradication efforts. Smallpox, the first global disease to be eradicated, was declared eradicated in 1980, through the successful efforts of the WHO Smallpox Eradication Campaign. The achievement of smallpox eradication resulted not only from the possession of an effective smallpox vaccine but also through global cooperation that used intensive surveillance, disease reporting, and aggressive focus on immunization in every local community. Malaria, a disease demonstrated first by Ronald Ross to be transmitted by mosquitoes, was targeted for eradication by the Malaria Eradication Campaign of the WHO, using basic strategies of personal protection, mosquito reduction, and treatment of malaria disease. Unfortunately, despite these effective means of prevention and treatment of malaria, malaria remains a global health problem because most rural or resource-poor communities have not adopted these preventive and curative health measures. This failure demonstrates the complexity of global health problems and highlights the interrelationships among health, infrastructure, culture, politics, and economics and emphasizes the importance of culturally sensitive programs. Other infectious diseases also now targeted for global eradication programs include polio, trachoma, tuberculosis, rabies, and HIV/AIDS.[30]

In the 1970s, a movement emphasizing primary health care in rural communities became increasingly popular. An example of such a movement was the "barefoot doctors" in China during the Cultural Revolution, who emphasized rural care and community-based health programs. In 1971, the NGO Doctors Without Borders was founded by French physicians who understood the importance of sociopolitical determinants of health. In 1978, the International Conference on Primary Health Care took place in Alma-Ata, the capital of the Soviet Republic of Kazakhstan, in the Soviet Union. From this conference emerged the Declaration of Alma-Ata, which stated that health was a fundamental human right and an important worldwide social goal and supported "Health for All by the Year 2000." It also emphasized the importance of culturally sensitive, local, community-based programs as opposed to top-down vertical programs that were previously used in the smallpox and malaria eradication campaigns.

From the broad concepts of primary health brought forth from the Declaration of Alma-Ata came selective and targeted goals for primary health care implementation. These programs included goals for measles and diphtheria-pertussis-tetanus vaccination, treatment of malaria, oral rehydration for diarrhea in children, encouragement of breast-feeding, and family planning. The goals, implementation, and success of targeted and focused strategies on specific disease prevention and treatment could also then be measured and assessed for political and philanthropic funding. Donations for global health were estimated to be over $10 billion dollars in 2000, and governments, agencies, companies, and individuals who fund global health initiatives now increasingly demand performance data in return for their financial aid.

Modern global health challenges include the ongoing balancing act between preventive public health initiatives and medical treatment interventions. A diagonal approach that synergistically incorporates both types of interventions is likely to be most successful. In addition, as industrialized development and economic progress spreads globally, the challenge will be to emphasize the importance of local cultural sensitivity and avoid resource exploitation that may occur at the expense of the health of the local people. Global health indicators to monitor changes in the health of various populations are being advocated for both developed and developing countries.[11-13] These indicators should be well defined and applied internationally in a uniform manner. They also should be valid, reliable, and readily interpretable measurements that can be feasibly gathered and affordably ascertained even in developing countries, and they should be useful to decision makers who can easily act on the indicators at the local, national, and international level. Health indicators in developed countries often reflect lifestyles and individual behavior, such as diet, exercise, and smoking, whereas health indicators in developing countries focus on morbidity, mortality, and severe disease precursors of both of these indicators.[21,22] Global health indicators are a contemporary challenge, especially in resource-poor areas with little or no access to electrical power and where records of birth, growth, lifestyle, medical illness, or death are not systematically recorded and kept.[21,22]

Global health communication, public health awareness, and humanitarian efforts are also now facilitated through Internet use, mobile cellular phones, mobile applications, and social media. Through the power of the periphery that social media and mobile cell phones provide, people are able to expand their community and access not only information but also health care and transportation. In addition, many global health care organizations use cellular phones in remote or resource-poor locations to collect research data for social health projects or instantaneously log information into surveillance systems for outbreak investigations.

SOCIAL DETERMINANTS OF HEALTH

The social determinants of health reflect where people are born, grow, live, work, and age and represent a powerful influence on the global health and the global disease burden of all nations.[35] Disease is often directly and indirectly influenced by other social, political, economic, and environmental factors, which in turn are responsible for ongoing health inequalities or acute and urgent health crises. These social determinants of health include broad and general political, socioeconomic, cultural, and environmental conditions; social and community networks; individual and family lifestyle factors; and individual characteristics such as age, gender, and genetic or constitutional factors (Table 230-2).[35]

TABLE 230-2 **Social, Environmental, and Individual Determinants of Health**

Socioeconomic, Political, and Cultural
Government
Politics
War
Refugees and displaced populations
Food security
Global connectivity through travel and Internet
Epidemics and pandemics both facilitated by travel and aborted by information exchange
Environmental
Global warming
Influences ecology and vector life cycles for hemorrhagic fevers
Natural disasters
Earthquakes, tsunami, hurricanes, volcanoes, floods, drought
Pollution
Industrial, fuel, wood-burning smoke
Water and sanitation
Agriculture and food production
Social and Community
Personal economic status
Housing or homelessness
Access to electrical power
Education opportunities, language, literacy
Child labor and child hawking practices
Transportation
Gender and age discrimination
Violence
Overcrowding
Access to health care and immunizations
Family and Individual Lifestyle
Employment or unemployment
Economic status
Chronic stress
Healthy food choices
Exercise
Smoking
Alcohol use or addiction
Drugs and addiction
Reproductive health and birth control
Individual Constitutional Factors
Prematurity and birth characteristics
Age
Gender
Physical health conditions
Sickle-cell hemoglobinopathy
Anemia
Malnutrition
Other chronic conditions
Mental health conditions

MILLENNIUM DEVELOPMENT GOALS FOR GLOBAL HEALTH

The Millennium Development Goals (MDGs) are eight broad global health goals established and agreed on by all U.N. Member States and 23 supporting organizations of the world during a U.N. summit in 2000 (Table 230-3).[31,32] The United Nations Millennium Declaration was adopted as a commitment to address the challenges facing human health globally and promote global development by improving social and economic conditions in the poorest countries, the "bottom billion," by the year 2015.[34,36,37] Goal four "to reduce child mortality" and goal five "to improve maternal health" specifically address pediatrics, and the sixth goal "to combat HIV-AIDS, malaria, and other diseases" specially addresses infectious diseases (Fig. 230-1).[19,25,30,32]

NEGLECTED TROPICAL DISEASES AND THE BOTTOM BILLION

The neglected tropical diseases (NTDs) refer to a group of 17 infections, 13 of which are bacterial and parasitic conditions, that are among the most common chronic infections and disabling conditions affecting the world's poorest and most disadvantaged people[9] (Tables 230-4 and 230-5). Whereas much global health attention has been paid to HIV/AIDS, malaria, and tuberculosis, as a result of the United Nations Millennium Declaration, the NTDs have not received as much attention or funding.[8,16,19] Nonetheless, eradication of NTDs would also support success toward the Declaration's global health goals. These NTDs are all infectious diseases that commonly infect infants, children, and adolescents.[14,17] Unlike acute infections, which often cause rapid mortality in developing countries, the NTD infections cause high morbidity but low mortality and result in chronic conditions that affect individuals for a lifetime. These affected individuals are often stigmatized or disfigured or unable to find work and income, further attributing to their cycle of poverty.

The NTDs are endemic in developing countries and commonly affect the "bottom billion," a term that refers to the poorest 2.7 billion people living in rural regions and poor urban areas, on less than U.S. $2.00 per day. By causing adverse effects on child development and learning, pregnancy outcome, and agricultural productivity, the NTDs are emerging as one of the most important groups of infections that trap the poorest people living in sub-Saharan Africa, Asia, and the Americas in a cycle of poverty and destitution. The NTDs both occur in the setting of poverty and promote and perpetuate

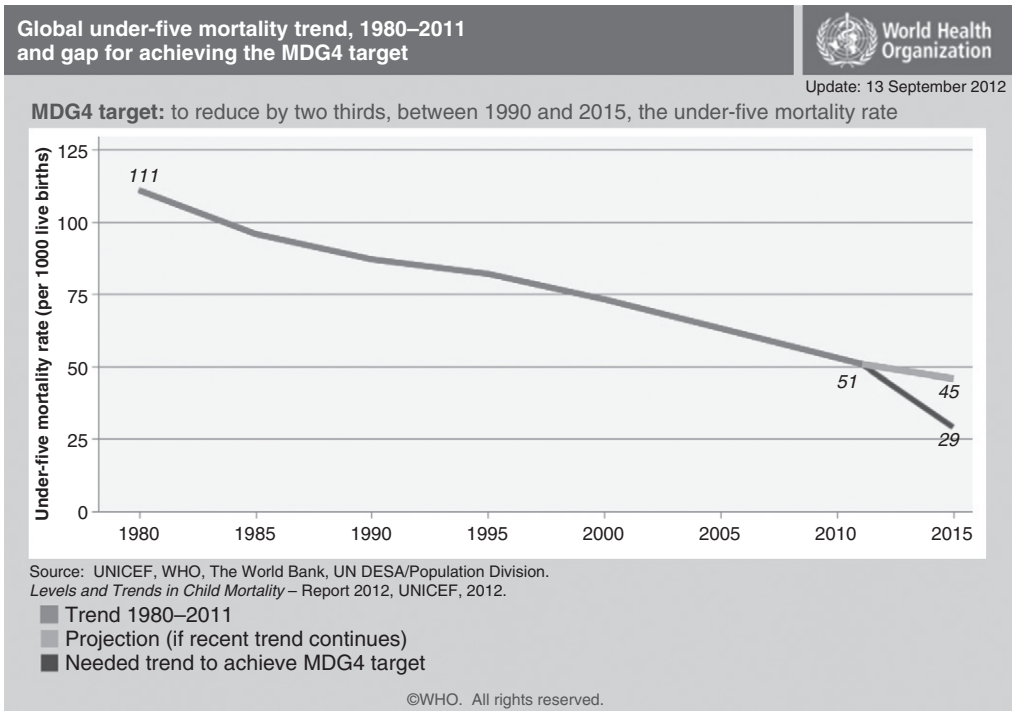

FIGURE 230-1 ■ Millennium Developmental Goal 4 to reduce child mortality. (From World Health Organization. Child health. Available at: http://www.who.int/gho/child_health/en/index.html.)

TABLE 230-3 Millennium Development Goals Adopted by World Leaders at the United Nations in 2000 To Be Achieved by 2015

1. Eradicate extreme poverty and hunger
   a. Halve the proportion of people living on less than U.S. $1 per day
   b. Achieve decent employment
   c. Halve the proportion of people suffering from hunger
2. Achieve universal primary education
   a. Allowing all children, regardless of gender, to complete a full course of primary schooling
3. Promote gender equality and empower women
   a. Eliminate gender disparity in primary and secondary education
4. Reduce child mortality
   a. Reduce the under 5 mortality rate by two thirds from the year 1990
5. Improve maternal health
   a. Reduce the maternal mortality rate by three fourths from the year 1990
   b. Achieve universal access to reproductive health
6. Combat HIV/AIDS, malaria, and other diseases
   a. Begin to reverse the spread of HIV/AIDS by 2015
   b. Achieve universal access to treatment of HIV/AIDS by 2010
   c. Begin to reverse the incidence of malaria and other major diseases by 2015
   d. Reduce tuberculosis worldwide
7. Ensure environmental sustainability
   a. Integrate the principles of sustainable development into country policy programs and reverse the loss of environmental resources
   b. Reduce biodiversity loss and achieve a significant reduction in the rate of loss
   c. Halve the proportion of the population without sustainable access to safe drinking water and basic sanitation
   d. Achieve a significant improvement in the lives of at least 100 million slum-dwellers
8. Develop a global partnership for development

TABLE 230-4 Neglected Tropical Diseases Caused by Bacteria or Parasites of Major Importance to Global Health

Ascariasis
Hookworm
Trichuriasis
Lymphatic filariasis
Onchocerciasis (river blindness)
Dracunculiasis (guinea worm disease)
Schistosomiasis
Chagas disease (American trypanosomiasis)
Human African trypanosomiasis (African sleeping sickness)
Leishmaniasis
Buruli ulcer (*Mycobacterium ulcerans* infection)
Leprosy (Hansen disease)
Trachoma

TABLE 230-5 Other Neglected Tropical Diseases of Importance to Global Health

Dengue fever
Cysticercosis
Echinococcosis
Foodborne trematode infections (i.e., clonorchiasis, fascioliasis, opisthorchiasis, paragonimiasis)
Yaws
Rabies
Leptospirosis
Strongyloidiasis
Scabies

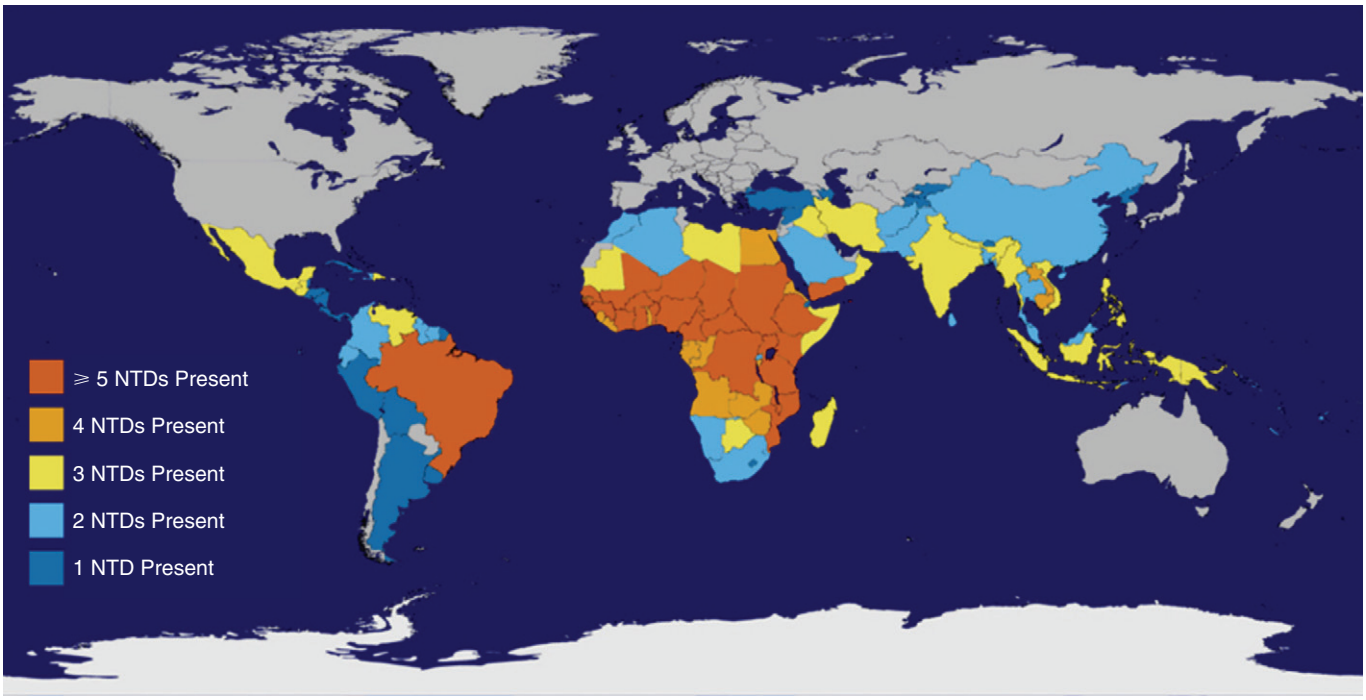

FIGURE 230-2 ■ Global map of six of the most common neglected tropical diseases burden (guinea worm disease, lymphatic filariasis, onchocerciasis, schistosomiasis, soil-transmitted helminths, and trachoma). (See companion Expert Consult website for color version.) (From Centers for Disease Control and Prevention. Neglected tropical diseases. Available at: http://www.cdc.gov/globalhealth/ntd/diseases/ntd-worldmap-static.html.)

poverty.[14-17] Caught in a poverty trap of dependence, debt, and disease, the bottom billion are directly affected by NTDs, economic failures, and lack of educational opportunities.[24] According to Paul Collier, director of the Centre for the Study of African Economies at Oxford University, these countries of the bottom billion have fallen into at least one of four possible traps: conflict, natural resources, landlocked next to bad neighboring countries, and bad governance in a small country.[24] This population lives within the rural regions and poor urban areas of roughly 58 countries, including Afghanistan, Angola, Azerbaijan, Benin, Bhutan, Bolivia, Burkina Faso, Burundi, Cambodia, Cameroon, Central African Republic, Chad, Comoros, Democratic Republic of the Congo, Republic of the Congo, Ivory Coast, Djibouti, Equatorial Guinea, Eritrea, Ethiopia, Gambia, Ghana, Guinea, Guinea-Bissau, Guyana, Haiti, Kazakhstan, Kenya, North Korea, Kyrgyz Republic, Lao Peoples' Democratic Republic, Lesotho, Liberia, Madagascar, Malawi, Mali, Mauritania, Moldova, Mongolia, Mozambique, Myanmar, Nepal, Niger, Nigeria, Rwanda, Senegal, Sierra Leone, Somalia, Sudan, Tajikistan, Tanzania, Togo, Turkmenistan, Uganda, Uzbekistan, Yemen, Zambia, and Zimbabwe.

The majority of people in the bottom billion are affected by at least one of the NTDs, often leading to long-term sequelae and disability.[24] Seven NTDs are of particular significance because even though they have high prevalence the ability to control the infection does exist. These include the soil-transmitted helminthes (i.e., hookworm, ascariasis, trichuriasis), lymphatic filariasis, schistosomiasis, and diseases causing blindness—trachoma, and onchocerciasis (Figs. 230-2 to 230-4).

FIGURE 230-3 ■ Woman from Republic of Sierra Leone, West Africa with onchocerciasis or "river blindness," a parasitic disease caused by *Onchocerca volvulus* and spread by the black simulian fly, which breeds in fast-flowing rivers. It is a leading cause of blindness and endemic in sub-Saharan Africa, as well as in parts of Yemen and Central and South America. The social implications of the disease affect not only adult independence and productivity but also children, who are denied access to education because they must stay at home and act as caretakers for the blind older relatives. (See companion Expert Consult website for color version.) (Courtesy Olivier Asselin, Sabin Vaccine Institute, Baylor College of Medicine, and Texas Children's Hospital, Houston, Texas.)

These diseases occur primarily in rural areas and in some poor urban settings of low-income countries in sub-Saharan Africa, Asia, and Latin America. Although the NTDs can affect anyone at any age, the seven most common diseases listed earlier often infect children, leading to a lifetime of disfigurement and disability,

FIGURE 230-4 ■ Toddler from Republic of Sierra Leone, West Africa, with distended abdomen and malnutrition caused by soil-transmitted helminth parasitic disease, one of the neglected tropical diseases. Disabilities associated with this disease include anemia and growth and cognitive delays. (See companion Expert Consult website for color version.) (Courtesy Olivier Asselin, Sabin Vaccine Institute, Baylor College of Medicine, and Texas Children's Hospital, Houston, Texas.)

which in turn leaves them without the ability to work effectively and thus caught in the poverty trap. Along with childhood disfigurement, other issues affecting quality of life are impaired childhood growth and development, adverse outcomes of pregnancy, and reduced productive capacity. Seven of the NTDs (lymphatic filariasis, onchocerciasis, schistosomiasis, trachoma, and the soil-transmitted helminthes *Ascaris*, hookworm and, whipworm) are considered "tool ready" to implement massive drug administration (MDA), as well as diagnostic and follow-up surveillance strategies. These targeted MTDs are the focus of many of the contemporary global and health efforts. For example, since the beginning of the guinea worm eradication program, the number of cases of guinea worm disease has decreased from an estimated 3.5 million cases in 20 countries in 1986 to fewer than 2000 cases in 2010. Other NTDs (i.e., Buruli ulcer, Chagas disease, cysticercosis, dengue fever, echinococcosis, fascioliasis, human African trypanosomiasis, leishmaniasis, leprosy, rabies, and yaws) are considered "tool deficient" because they lack one or more of the components necessary to deliver an effective MDA campaign.

FUTURE DIRECTION OF GLOBAL HEALTH

The future directions of global health include collaborative progress by medical and public health teams, industry, world leaders, governments, NGOs, and private nonprofit philanthropy organizations toward the ambitious set of eight Millennium Development Goals to eliminate extreme poverty, hunger, and disease by the year 2015 (Figs. 230-5 through 230-10).[1]

In addition, advances in technology for diagnosis, treatment, and prevention of diseases of global importance, application of new technologies into global public health practice, education of new generations of global health scientists and global public health experts to develop and apply these new technologies to global health, and expansion of Internet and mobile applications to reach and educate people in developing world.[18]

An example of a rapidly emerging development in diagnostics in the field is "lab-on-a-chip" (LOC) technology, which may soon become an important part of efforts to improve global health, particularly through development of point-of-care testing devices. In poorly equipped clinics in resource-poor countries, treatable infectious diseases soon may be accurately diagnosed by clinicians using immunoassays and nucleic acid assays performed by microfluidic LOC technology, allowing appropriate treatments to be administered. For example, accurate diagnosis of HIV infection and measuring the number of CD^+ T lymphocytes, with resultant antiretroviral treatment, may soon be possible with LOC brought to resource-poor areas where most of the untested, untreated HIV-infected individuals reside.[8,25] For the chips to be used in areas with limited resources, many challenges must be overcome. In developed nations, the most highly valued traits for diagnostic tools include speed, sensitivity, and specificity; but in countries where the health care infrastructure is less well developed, attributes such as ease of use and shelf life must also be considered. If LOCs are to be used in the resource-poor areas of the developing world, their reagents must have a long shelf life at tropical room temperatures, as well as have low cost, scalability and recyclability.

Trainees in undergraduate and postgraduate courses in public health, medical schools, and medical residencies and fellowships, as well as students in schools for nursing and physician assistant training have a growing interest in understanding the major factors that influence global health of individuals and populations worldwide.[26-29] Most medical schools and public health institutions are developing global health essential core competencies to provide their students with basic understanding of the complexity of global health issues, especially in low-resource settings, and the control of diseases of importance to global health.[10,26] In addition to studies in the classroom, many institutions now provide practical experience in international settings and global health career path training (Fig. 230-11).[29] A new National School of Tropical Medicine (NSTM) was recently established in 2012 in Houston, Texas, providing a North American counterpart to the century-old Liverpool School of Tropical Medicine and the London School of Hygiene and Tropical Medicine.[15] The mission of the NSTM includes training global health scientists and global health care providers in the area of tropical medicine and to develop and deliver new generations of technologies in vaccines, drugs, and diagnostics for infections associated with

FIGURE 230-5 ■ **A,** River scene near the rural town of Doma in Nasarawa State of Nigeria, showing men, women, and children using river water for washing. The river also may be used to wash motorcycles and cars and even for drinking. Providing access for the world's people to safe and clean water for drinking and washing is one of the Millennium Developmental Goals for 2015. **B,** Orphan girl at the Kang'oma orphanage and daycare center near Mzuzu, Malawi takes a drink from a new water well and hand-pump built by U.N. volunteers in August 2012. The well provides access to clean water for drinking and washing and helps prevent diarrheal diseases, dehydration, trachoma, and other diseases. Malawi is one of the poorest host countries in the "bottom billion." To halve the number of people without access to clean water and sanitation is one of the Millennium Development Goals to be achieved by 2015. **(See companion Expert Consult website for color version.)** (**A,** Courtesy Dr. Gail Harrison. Photograph taken during a medical mission cosponsored by Ntwatwa Global Services, Houston, Texas and the Onawa Medical Mission Project of Nasarawa State, Nigeria in December of 2011. **B,** Courtesy Byron McCord and Holly Corwin.)

FIGURE 230-6 ■ Children gathered in front of the medical and surgical cottage hospital in Doma, Nasarawa State, Nigeria. Many children are shown with water, melons, and cashews in baskets balanced on their head, which they sell to local people through street trading or hawking. This practice is common in Nigeria; although it allows a means to make an income for their family's survival, it also often keeps the children from attending school and receiving an education, perpetuating the cycle of poverty. To achieve universal primary education is one of the Millennium Development Goals for 2015. **(See companion Expert Consult website for color version.)** (Courtesy Dr. Gail Harrison. Photograph taken during a medical mission cosponsored by Ntwatwa Global Services, Houston, Texas and the Onawa Medical Mission Project of Nasarawa State, Nigeria in December of 2011.)

FIGURE 230-7 ■ Surgical procedures performed in remote areas of the world often must be done under stark and challenging conditions. This 3-year-old boy from Doma, Nasarata State, Nigeria is having a right inguinal herniorrhaphy performed, under ketamine anesthesia, by local physicians in an operating room in Doma Hospital, Nasarata State, Nigeria. The procedure was successfully completed, he awakened, and received a post-operative intramuscular injection of an antibiotic to prevent infection. **(See companion Expert Consult website for color version.)** (Courtesy Dr. Gail Harrison. Photograph taken during a medical mission cosponsored by Ntwatwa Global Services, Houston, Texas and the Onawa Medical Mission Project of Nasarawa State, Nigeria in December of 2011.)

FIGURE 230-8 ■ Evaluating and treating patients for infectious diseases in remote rural areas is challenging, because microbiologic cultures, laboratory tests, diagnostic imaging, biopsies, and intravenous infusions are not available. In this photograph, the author, using natural light provided through a window, explains the findings of a plain radiograph showing destructive bone changes of the proximial right femur, consistent with chronic osteomyelitis. The patient, an 11-year-old boy, had a 2-year history of painful limp, chronic draining fistulous tracts, and tenderness over the proximal femur. Lack of money and access to transportation precludes accessing medical care with specialists in an urban hospital. The child was provided with crutches to help ease pain and facilitate mobility, and a 3-month supply of oral antibiotics. He also was given a "written referral" to a specialist in the medical center in Abuja, Nigeria, but unless he is able to travel to the larger urban center, his next follow-up will be in 1 to 2 years at the next medical mission. (See companion Expert Consult website for color version.) (Courtesy Dr. Gail Harrison. Photograph taken during a medical mission cosponsored by Ntwatwa Global Services, Houston, Texas and the Onawa Medical Mission Project of Nasarawa State, Nigeria in December of 2011.)

FIGURE 230-9 ■ Medical wards in hospitals in remote, resource-poor, rural areas of the "bottom billion" countries, are often stark, are maintained as well as possible with available resources, and lack modern equipment to which health care providers in resource-rich countries are accustomed. (See companion Expert Consult website for color version.) (Courtesy Dr. Gail Harrison. Photograph taken during a medical mission cosponsored by Ntwatwa Global Services, Houston, Texas and the Onawa Medical Mission Project of Nasarawa State, Nigeria in December of 2011.)

FIGURE 230-10 ■ This 13-year-old Nigerian girl had a several-year history of increasing kyphosis. A soft, nontender mass was palpated along her spine. The presumptive diagnosis was Potts disease, a presentation of extrapulmonary tuberculosis that most commonly affects the lower thoracic and upper lumbar vertebrae of the spine. The sixth goal "to combat HIV-AIDS, malaria, and other diseases" of the Millennium Development Goals specifically addresses the health and economic impact of infectious diseases on global health. It includes programs specifically targeted to combat tuberculosis.[30] (See companion Expert Consult website for color version.) (Courtesy Dr. Gail Harrison. Photograph taken during a medical mission cosponsored by Ntwatwa Global Services, Houston, Texas and the Onawa Medical Mission Project of Nasarawa State, Nigeria in December of 2011.)

FIGURE 230-11 ■ Dr. Gelane Workneh, *left,* works with residents and medical students as she make rounds in the pediatric ward at University of Gondar Hospital (October 11, 2011) in Ethiopia. Dr. Workneh is one of three doctors Texas Children's Hospital Global Health Corps physicians and the Baylor College of Medicine Pediatric AIDS Initiative provides to work with the Jewish Joint Distribution Committee and Gondar University College of Health Sciences in Gondar as part of a 3-year grant. These doctors work to expand pediatric medical capacity in Ethiopia by teaching medical students and interns from Gondar University and by training local health care professionals. Global health experiences have become an important part of medical education curriculum in many major medical centers. (See companion Expert Consult website for color version.) (Courtesy Smiley N. Pool and BIPAI, Houston, Texas. Copyright 2011.)

poverty and the poorest people in the lowest income countries of the world.[15]

The future of communication and information technology also includes global health. Social media provides unprecedented connectivity because even in the most resource-poor areas of the world, fragmented levels of power and Internet access are available (Fig. 230-12).[31] Social media are being used by philanthropic organizations, such as the Bill and Melinda Gates Foundation, to update their donors and partners on measureable markers of progress toward defined global health goals.[23] Mobile global health education applications, linking smart phones and pico projectors and other mobile technology, have the potential to be inexpensive, sustainable, ubiquitous, acceptable, and therefore effective in disseminating information on a global scale, linking resource-rich areas with remote, resource-poor areas of the world. In addition, mobile devices may be used for surveillance[33] of infectious diseases, as well as chronic conditions such as heart disease, hypertension, and diabetes. Mobile devices also may be used for global health surveys and health information systems management. Mobile technology is also ideal for providing rapid scientific, epidemiologic, and public health knowledge at the time of a disaster. Mobile technologies may soon revolutionize global health care because individuals who are patients in resource-poor remote areas also may own or borrow mobile phones, allowing communication to access health care when needed, and reducing mortality.[32] As an example of creative adaptability, in "light-poor" communities and villages who do not have reliable electrical power at night, the light provided by individual cell phones allows health care providers to assist in medical procedures, including deliveries of babies at night.[31]

FIGURE 230-12 ■ Internet access through personal computers, local "dot-com" Internet cafes, and handheld mobile devices has reached even the most remote areas of the world and provides creative opportunities to improve global health and awareness in these remote communities. CHAPTER 231

International Travel Issues for Children

Michelle Weinberg • Nicholas Weinberg • Susan A. Maloney

During the past half-century, the number of persons traveling internationally has increased tremendously. Between 1980 and 2011, the number of international arrivals worldwide more than tripled, growing from 277 million to 983 million. In 2010, more than 28 million U.S. residents traveled overseas; of these residents, almost 23 million were traveling for leisure or visiting family and friends. Although the exact number of children traveling is unknown, 2.2 million (8%) of these U.S. travelers were adults and children traveling together and 3.1 million (11%) reported their occupation as students.[137] Among the more than 28 million U.S. resident travelers, 9.5 million (34%) visited Europe, 6.1 million (22%) visited the Caribbean, 5.6 million (20%) visited Asia, 4.2 million (15%) Central and South America, 1.6 million (6%) visited the Middle East, 840,000 (3%) visited Africa, and 560,000 (2%) visited Oceania.[136,157] Worldwide, Europe and Asia and the Pacific region were the fastest-growing destinations in terms of international tourist arrivals, and each grew more than 6 percent in 2011.

Study abroad by U.S. students enrolled in higher education has also tripled in the last 20 years; more than 270,000 U.S. students studied abroad during the 2009 to 2010 school year.[89] The United Kingdom, Italy, Spain, France, and China were the top host destinations; however, the number of students studying in Africa, Asia, and the Middle East increased by more than 8 percent each and nearly 14,000 students studied in China.[89]

International travelers may be exposed to a variety of health risks, depending on the travel destination, trip itinerary, duration of stay, planned travel activities (i.e., business vs. adventure), individual risk factors, and preventive measures taken. For persons from industrialized countries visiting developing countries, travel may expose them to a variety of infectious pathogens and environmental hazards, some of which they may rarely encounter at home. Despite the well-documented health risks associated with international travel, surveys have shown that many travelers do not seek pretravel health advice or obtain appropriate travel-related preventive medications or vaccinations. Surveys of U.S., European, and Australian travelers have shown that only 31 to 52.1 percent of the travelers sought travel advice before the trip. In an airport survey of 203 U.S. passengers traveling to high-risk, malaria-endemic areas, only 46 percent were carrying antimalarial medications with them[78,139,147] and few were vaccinated for their travel—only 11 percent for tetanus, 14 percent for hepatitis A, 13 percent for hepatitis B, and 5 percent for yellow fever.[78] Among 1704 respondents from the 2008 YouthStyles survey, an annual mail survey of demographics and health knowledge,

attitudes, and practices of youth 9 through 18 years of age, 131 (7.7%) traveled in the last 12 months; of these travelers, only 16.7 percent reported seeking pretravel medical care, mostly (84%) from a family doctor.[79] In a survey of 318 American students studying abroad, the primary source of travel health information was reported to be youth-oriented travel guidebooks (85%).[80]

Travelers who are visiting friends and relatives are at high risk for acquiring a variety of illnesses and are less likely to seek pretravel medical advice.[7-9,44,99] In a review of travelers seeking medical care for travel-related illnesses in the GeoSentinel Surveillance Network, only 16 percent of those who were immigrants and were visiting family and friends sought pretravel medical advice.[99] Systemic febrile illnesses (including malaria), nondiarrheal intestinal parasitic infections, respiratory syndromes, tuberculosis, and sexually transmitted diseases (STDs) were more commonly diagnosed among immigrants visiting friends and relatives than in other travelers, whereas acute diarrhea was less frequent. In contrast to other travelers, the immigrants who were visiting friends and relatives were more likely to travel to sub-Saharan Africa or Latin America and to take a trip lasting longer than 30 days.[99] In a review of travelers presenting at one GeoSentinel Surveillance Network clinic site, the proportion of travelers with malaria who had been visiting friends and relatives was eight times greater than among tourists (16.9% vs. 2.1%).[97]

PEDIATRIC TRAVELERS AND HEALTH RISKS ABROAD

Information is limited on the causes of serious morbidity and mortality among pediatric travelers, and efforts to collect these data should be undertaken to direct prevention measures so that morbidity and mortality rates in pediatric travelers can be decreased.[12,77,84,114,122] However, recent studies have identified several major categories of morbidity among pediatric travelers: diarrheal illnesses, respiratory diseases, dermatologic conditions, and systemic febrile illnesses. Herbinger and colleagues[82] reviewed data from 890 children younger than 20 years of age at an outpatient travel clinic at the University of Munich, Germany after travel to Africa (46%), Asia (35%), and Latin America (19%). The most frequent syndromes were acute diarrhea (25%, especially in children ages 0 to 4 years of age), dermatologic conditions (19%, especially in children ages 0 to 9 years), febrile and systemic diseases (20%), respiratory disorders (8%), chronic diarrhea (5%), and genitourinary disorders (3%). The 10 most frequently diagnosed infectious diseases were giardiasis (8%), schistosomiasis (4%), superinfected insect bites (4%), *Campylobacter* enteritis (4%), *Salmonella* enteritis (4%), cutaneous larva migrans (3%), amebiasis (3%), dengue fever (2%), mononucleosis (2%), and malaria (2%).[82] Hunziker and colleagues[85] reviewed data from 328 children ages 16 years and younger with travel-associated illness at the emergency room of the University of Zürich Children's Hospital. The main conditions were diarrheal illness (39%), respiratory (28.7%), and systemic febrile illness (13.4%). No deaths were reported. Among 36 children with more serious diseases requiring hospitalization, 12 (3.7% overall) had potentially serious diseases: malaria (n = 2), *Salmonella typhi* (n = 3), *Salmonella paratyphi* (n = 2), meningococcal meningitis (n = 1), tuberculosis (n = 2), visceral leishmania (n = 1), and hepatitis A (n = 1). Eleven of the 12 children with serious diseases were visiting friends and family or immigrant children.[85] Van Rijn and colleagues[140] conducted a prospective observational cohort study of 152 children and their parents traveling to the tropics and subtropics; 85 percent of all children reported some kind of aliment during travel, with a mean aliment rate of 7.0 ailments per person-month of travel. The most frequently reported ailments were skin problems, including insect bites, sunburn, and diarrhea.[140]

Other authors have reported substantial health risks for pediatric travelers from noninfectious causes such as injuries. Most deaths are associated with swimming or automobile accidents.[84,101] One study of British children drowning abroad while traveling showed that an average of eight British children drown each year abroad, primarily in swimming pools without adequate lifeguards.[64]

Although some data from adult travelers can be extrapolated to use in the management of pediatric travelers, infants and children have special vulnerabilities and needs when preparing for travel abroad. These needs include (1) up-to-date and appropriate vaccinations (at times through accelerated or altered routine childhood vaccine schedules and also including special travel-related vaccines); (2) appropriate malaria and other chemoprophylaxis regimens tailored for use in pediatric travelers; (3) prevention counseling, particularly in the areas of food and water safety, insect barriers, and injury prevention; and (4) anticipatory guidance for the management of potential illness and successful location of medical resources overseas. This chapter provides recommendations for conducting a pediatric pretravel assessment to ensure that the child has received the appropriate vaccination and chemoprophylaxis regimens, pretravel prevention counseling, and means of accessing additional sources of travel information about health risks and the availability of medical resources at specific travel destinations.

GENERAL APPROACH TO PRETRAVEL ASSESSMENT FOR CHILDREN

Before embarking on international travel, children should have a pretravel health assessment performed by a health care provider. The number of physicians who specialize in travel medicine for children is relatively limited, and many pretravel assessments are performed by general pediatricians, pediatricians who specialize in infectious diseases, or travel medicine specialists without specific pediatric training. The visit should be conducted with the goal of preventing travel-related illnesses. Depending on the destination and the vaccinations recommended or required, the assessment should be conducted optimally 1 to 6 months before travel. Because families may not be aware of the need for multiple vaccinations and medications, health care providers should be proactive and

routinely ask patients and their families if they are anticipating any international travel in the next several months, especially before holiday periods.

During the pretravel assessment, the provider should do the following:

1. Review the child's current and past medical history, including the status of routine childhood vaccinations.
2. Obtain specific details about the travel itinerary and planned activities. Review endemic diseases and recent outbreaks in travel destinations.
3. Administer indicated routine and travel-related vaccinations.
4. Prescribe antimalarial, other prophylactic or self-treatment medication (based on risk assessment from the medical history, travel itinerary, and planned activities).
5. Counsel about prevention of travel-related illnesses.
6. Provide guidance about seeking medical assistance for travel-related illness.

The age, immunization status, and medical history of the child are important information to have in conducting the pretravel assessment. The provider should consider three categories of vaccinations: routine childhood vaccinations, required travel-related vaccinations, and recommended travel-related vaccinations. Some routine vaccinations should be administered at an earlier age or after an accelerated schedule in preparation for international travel. In addition, the provider should review and administer travel-related vaccinations that are required for entry by various countries to prevent the importation of disease and development of outbreaks, as well as vaccinations recommended for the prevention of illness in the individual traveler.[32] Currently, only two vaccines—yellow fever and meningococcal—are required for entry by selected countries; however, these requirements may change in the future. In addition, some countries require documentation of human immunodeficiency virus (HIV) testing before allowing entry of long-term travelers (see discussion on international travel information resources). Guidelines for standard and accelerated schedules for routine childhood immunizations and for required and recommended travel-related vaccinations by specific travel destinations are summarized in this chapter in the section on vaccination for international travel. A review of medical conditions and contraindications is critical before vaccinations are administered or medications such as antimalarial chemoprophylaxis are prescribed.

The pretravel assessment should include a detailed review of the trip itinerary. The health care provider should ask about sources of water and food (homes vs. hotel restaurants), type of accommodations (e.g., camping, hotel chains, or residing with local families), amount and type of contact with the local population, and planned activities during travel (adventure travel with exposure to animals, water, high altitude, or any combination of these factors). Recommendations to prevent vector-borne diseases, including malaria, should be determined by a comprehensive review of the travel itinerary and planned activities. Guidance for determining appropriate regimens for antimalarial chemoprophylaxis in pediatric travelers is provided in this chapter in the discussion on malaria prevention. The risk for acquiring an infectious disease differs and is probably greater for an adolescent who is participating in a rural home-stay program for 3 months than for a 5-year-old child traveling with parents to a beach resort. Furthermore, expatriates who live abroad and foreign-born persons, especially immigrants, refugees, and their children visiting friends and relatives in their home country, have health risks different from those of short-term travelers who are visiting tourist destinations. These differential risk profiles should be taken into account during the pretravel assessment because such knowledge is essential for devising a specific pretravel management plan.

On the basis of risk assessment, preventive health counseling should include information about food and water safety, prevention of vector-borne illnesses, and other infectious and noninfectious illnesses, such as sexually transmitted infections and automobile accidents. General and specific prevention counseling recommendations are addressed later in the chapter. In addition, families should clarify with their health insurance company whether they are covered for health care provided abroad. If not, insurance can be purchased from several companies; such insurance may include coverage for health care providers in a specific country and airlift medical evacuation. If assistance for illness acquired abroad is needed, the U.S. embassy or consulate can provide names and addresses of English-speaking health care providers at the travel destination. This information can be obtained before departure by accessing embassy Internet sites or by calling the embassy. In addition, names of physicians abroad can be obtained from some worldwide directories (see the discussion on international travel information resources). Parents should be told to carry all health-related documents with them for easy retrieval, including written prescriptions for medications, health insurance information, and medical contacts abroad. Counseling on ensuring the use of sterile needles and the safety of the local blood supply also should be included in pretravel prevention counseling topics; blood screening and infection control practices may not be as stringent in some countries as in the United States.

Special consideration must be given to children who have chronic diseases. Children with medical conditions should take a summary of their medical history and treatment record. If the child has cardiac disease, the family should consider taking a copy of the child's recent electrocardiogram and echocardiography report. Children with diabetes who are traveling through more than one time zone should consult their pediatrician or endocrinologist for guidance on the need for altering insulin dosing. Prescription medications should be carried in original bottles, and a sufficient supply for the length of the planned trip and a few extra doses should be packed. Required medications should be carried on the plane rather than packed in luggage because bags may be lost or exposed to unfavorable environmental conditions. Families should be counseled about the potential hazards of obtaining medications in pharmacies in developing countries, where many medications can be purchased

over-the-counter without a prescription and where the names, content, and concentration of medications may be different from those of U.S. products. Parents carrying medical equipment (such as nebulizers) should remember to take adaptors for foreign electric current and bring a letter from a physician that documents the need for the equipment.[39] Similar documentation is encouraged for anaphylaxis kits or other medications that require syringes.

VACCINATION FOR INTERNATIONAL TRAVEL

Vaccination before international travel is among the most critical and complex components of the pretravel assessment for children. The pretravel assessment should include a review of both recommended routine childhood vaccinations and required and recommended travel-related vaccines. Vaccination recommendations change rapidly. Whereas this section provides guidance as of publication date, clinicians should obtain the most current recommendations available on the Centers for Disease Control and Prevention (CDC) website (see the discussion on international travel information resources).

Routine Childhood Vaccinations for Pediatric Travelers

For children who will be traveling internationally, having their routine immunizations brought up to date is essential because many vaccine-preventable diseases are more prevalent in developing countries than in the United States. In particular, children who have nonmedical exemptions to routine vaccinations may be at high risk for acquiring vaccine-preventable diseases, such as measles and rubella, that no longer are endemic in the United States but still occur frequently in other countries. The pretravel visit also may give the health care provider a unique opportunity to update the routine vaccination status of a patient who has fallen behind schedule. In certain cases, routine vaccinations may need to be accelerated to maximize protection, particularly against polio, diphtheria-tetanus-pertussis, varicella, and measles (e.g., measles vaccination is recommended for children 6 through 11 months of age).[40,121] Many vaccine series can be initiated as early as 6 weeks of age. The management plan for routine vaccinations will be determined by the travel destination and itinerary. For example, diphtheria and pertussis are prevalent in Eastern Europe and many developing countries, and measles is still endemic in the developing world and some European countries; therefore, if travel to these countries is planned, ensuring immunity is imperative, and accelerated schedules should be considered. In addition, parents should check their own immune status because traveling with children can increase their risk for exposure to measles and other vaccine-preventable diseases.[86,87]

Measles was declared eliminated in the United States in 2000. However, travelers to Europe, Asia, the Pacific, and Africa continue to be at risk. High two-dose mumps, measles, and rubella (MMR) vaccine coverage is essential for travelers to prevent measles importation and outbreaks in the United States. In 2011, 222 cases of measles were reported in the United States; these cases were associated with 17 outbreaks in the United States and represent an increase in contrast to a median of 60 (range, 37 to 140) cases and four (range, 2 to 10) outbreaks reported annually during 2001 to 2010.[55] Of the 222 cases, 200 (90%) were associated with importations from other countries, including 52 (26%) cases in U.S. residents returning from abroad. Of the 200 cases associated with importation, 72 (36%) were importations from other countries, 67 (30%) were linked epidemiologically to importations, 39 (20%) had virologic evidence (i.e., isolation of a viral genotype known to circulate in a country with measles) that suggested recent importation, and 22 (11%) were linked to cases with virologic evidence of recent importation. Among the 72 cases of measles importation, 52 were linked to U.S. residents who traveled abroad. Almost half (46%) of the 72 measles importations occurred among persons who acquired the disease in the World Health Organization (WHO) European Region, which reported more than 30,000 cases in 2011. The highest number of cases, 16 (22%) were associated with importation from India, followed by 13 (18%) associated with importation from France. Most cases (86%) occurred among persons who were unvaccinated or had unknown vaccination status.[55] In 2005, importation of measles by an unvaccinated U.S. traveler led to one of the largest outbreak of measles in the United States since 1996 and involved 34 confirmed cases. The index case was a 17-year-old student who had a nonmedical vaccination exemption and was working as a missionary in an orphanage in Romania, where a large measles outbreak subsequently was reported.[119] Numerous cases of serologically confirmed measles also have occurred among internationally adopted children and their new parents and siblings who had traveled to China to accompany them home. Data suggest that the exposure to measles occurred in China, probably at the orphanage, where an outbreak of measles was occurring.[36,37] The MMR vaccine is administered routinely to children starting at 12 months of age. However, the MMR vaccine should be administered to children 6 to 11 months of age who are traveling internationally. These children should be revaccinated with two doses of MMR vaccine—the first at ages 12 through 15 months and at least 4 weeks after the previous dose and the second at ages 4 through 6 years. Children older than 12 months of age who are traveling internationally should receive the second dose, as long as 4 weeks have passed since the previous dose; even if administered before 4 years of age, this second dose counts toward the routine vaccination and does not need to be repeated at a later age. Providers should remind their patients who plan to travel internationally of the increased risk for measles and potential exposures during bus, train, or air travel and at large international events or gatherings.

Hepatitis A is endemic in most of the world, and travelers are at risk in any area where sanitation is poor. In 2006, hepatitis A vaccination became part of routine

childhood recommendations in the United States for all children at 1 year of age (12 through 23 months), supplementing recommendations in 1999 for vaccination of children 2 to 18 years of age residing in states and communities with high incidence of disease and other high-risk groups. In addition, hepatitis A vaccine is now routinely recommended for all previously unvaccinated children aged 24 months or older for whom immunity is desired. Vaccination is recommended for pediatric travelers 1 year of age or older who will be visiting countries with intermediate to high endemicity, such as Mexico, Central and South America, Asia, Africa, and eastern Europe.[39,41,56] Hepatitis A vaccine is administered as a two-dose series. The first dose of hepatitis A vaccine should be administered at least 14 days before travel. Limited data are available about the timing of the appearance of neutralizing antibody. Among a sample of vaccinated persons, 54 to 62 percent were positive for neutralizing antibody 14 days after the first dose, and 94 to 100 percent were positive at 1 month.[41] The second dose can be administered 6 months after the first dose. Intramuscular immunoglobulin is recommended for immunoprophylaxis against hepatitis A in children younger than 1 year of age. In addition, for children 1 year of age or older who will be departing sooner than 2 weeks after the pretravel visit (and therefore may not have sufficient time for immunity to develop after hepatitis A vaccination), both immunoglobulin and vaccine can be given concurrently at different sites to ensure more immediate protection. Shortages of immunoglobulin have occurred in the past, so obtaining it for hepatitis A prophylaxis may be difficult.[56] Hepatitis A outbreaks also have occurred among adoptees and their contacts, leading to American Academy of Pediatrics and the Advisory Committee on Immunization Practices recommendations for hepatitis A vaccination for all household members and close contacts, including babysitters, when children are adopted from countries with high or intermediate rates of hepatitis A infection. All nonimmune, unvaccinated people who will have close exposure to international adoptees during the 60 days after their arrival (regardless of whether they travel) should receive hepatitis A immunization, ideally 2 or more weeks before arrival of the adopted child.[6,42]

Worldwide polio eradication efforts have decreased the number of countries where travelers are at risk for acquiring polio. In 2011, 650 cases of wild poliovirus were reported from 16 countries; however, wild poliovirus is considered endemic in only three countries: Afghanistan, Nigeria, and Pakistan. India, which was previously on the list of endemic countries considered to have never interrupted the transmission of wild poliovirus, was declared free of endemic transmission in February 2012, 1 year after the last reported case occurred in January 2011. Between January 2012 through June 2012, cases were reported in Chad, Kenya, Niger and Somalia. However, countries associated with imported cases are continuously changing.[35,123] To ensure protection, pediatric travelers visiting countries where polio is epidemic or still endemic should be fully immunized, and young adults ages 18 or older should receive one booster dose of inactivated polio vaccine (IPV) if traveling to areas with risk of transmission. Clinicians should obtain up-to-date information about areas of transmission from the WHO or CDC (see discussion on international travel information resources).

Respiratory tract infections caused by influenza are a major cause of illness among travelers.[98] Influenza can occur throughout the year in tropical countries. Peak influenza rates in temperate regions of the Southern Hemisphere occur from April through September. In North America, influenza vaccine may not be available during the summer months. All children 6 months of age and older should have routine influenza vaccination annually. Travelers to the Southern Hemisphere should be vaccinated by the spring, if possible. Influenza vaccinations should be considered for travelers who are at high risk for complications from influenza for travel to (1) the tropics any time of year, (2) the Southern Hemisphere from April through September, (3) any destination with large groups of tourists at any time of year, or (4) any destination where influenza outbreaks are occurring.[41] In 2009, pandemic H1N1 outbreak emerged in Mexico and spread quickly around the world through travel. Protection against H1N1 is included in seasonal influenza vaccine.[46,48]

Meningococcal disease occurs sporadically worldwide. Epidemic disease has been reported in India, Saudi Arabia, and sub-Saharan Africa; indeed, recurrent epidemics of meningococcal disease occur in sub-Saharan Africa, mainly from December to June (the dry season). Serogroup A is the most common cause of epidemics outside the United States, but serogroup C and other serogroups also have been associated with epidemics. Serogroup W-135 meningococcal infection has been reported in travelers returning from Saudi Arabia after visiting the Hajj.[136] Three meningococcal vaccines, a polysaccharide vaccine (MPSV4), and two conjugate vaccines (MCV4-D and MCV4-CRM), are available in the United States. Both conjugate vaccines are quadrivalent and effective against serogroups A, C, Y, and W-135. MCV4 (either MCV4-D or MCV4-CRM) is recommended for routine childhood vaccination in the United States for (1) all children at the 11- to 12-year-old visit, with a booster at 16 years of age, (2) unvaccinated adolescents at 13 through 18 years of age, with a booster at 16 through 18 years; and (3) two-dose primary series administered 2 months apart for children 2 through 54 years of age with persistent complement component deficiency or anatomic or functional asplenia and for adolescents with HIV infection, followed by a booster every 5 years. Meningococcal vaccination is recommended for pediatric travelers 9 months of age or older who are visiting sub-Saharan Africa during the dry season or any country that is hyperendemic or where an epidemic caused by a vaccine serogroup is occurring. MCV4-D is licensed for use for children starting at 9 months of age, and MCV4-CRM can be used for children starting at 2 years of age. For children 9 through 23 months of age, MCV4-D should be administered as two primary doses; the second dose is recommended 3 months after the first dose, but the minimal interval between the first and second doses is 8 weeks. For children 24 months to through 10 years of age, two doses of either MCV4-D or

MCV4-CRM should be administered at least 8 weeks apart. See Table 231-1 for additional information. For children traveling to areas with risk for transmission, revaccination with MCV4 is recommended after 3 years for children who were previously vaccinated at ages 9 months to 6 years. Revaccination with MCV4 is recommended after 5 years for people who were previously vaccinated at 7 years of age and older and every 5 years thereafter for people who are at continued risk. Although it is less immunogenic than when it is administered to older children and adults, MPSV4 also can be used in children as young as 3 months to provide protection against serogroup A, such as travelers to areas with an epidemic or during seasonal transmission. These children should have two doses, 3 months apart.[51-53,57,57,121]

Hepatitis B, *Haemophilus influenzae* type b, rotavirus, *Streptococcus pneumoniae*, varicella, and human papillomavirus are endemic in many developing countries, and vaccination should be ensured.[47] For persons 18 years of age and older, a combination hepatitis A and hepatitis B vaccine (Twinrix) can be administered to travelers who need both vaccines. It is administered as a standard three-dose schedule at 0, 1, and 6 months after the first dose or can be accelerated at 0, 7, or 21 to 30 days, followed by a booster dose at 12 months.[43] Travel in large groups on conveyances such as cruise ships can facilitate the transmission of infectious and vaccine-preventable diseases.[105] The CDC has provided consultation on managing outbreaks of varicella and meningococcal disease in pediatric travelers on international cruise ships (CDC, unpublished data, 2013). For detailed information about accelerating routine childhood vaccinations and indications for use in pediatric travelers, see Table 231-1.

Common Travel-Related Vaccines for Children

An important consideration in determining travel vaccination needs is "required" versus "recommended" vaccinations. The most recent travel requirements and recommendations for vaccinations can be obtained from the CDC Travelers' Health Internet site (see the discussion on international travel information resources). Few vaccinations are required. The United States does not require arriving travelers to have any vaccinations for entry or return to the United States. However, immigrants, refugees, asylum seekers, and internationally adopted children migrating to the United States for permanent residence have different requirements. Some other countries may require proof of vaccination against yellow fever for entry, especially if the traveler is arriving from a country where yellow fever is present. Yellow fever vaccine is available only from certified yellow fever vaccination centers; providers can contact their state public health department to locate certified centers in their areas. Saudi Arabia requires meningococcal vaccine for travelers visiting Mecca for the Hajj or for the Umrah.[28,38,53] Some countries previously have required cholera vaccination, but currently no countries require vaccination as a condition of entry.[156] However, non-U.S. customs officials who "unofficially" request proof of vaccination have been reported. Cholera vaccine is not currently available in the United States but is available in Europe and other countries. Cholera is rare in travelers, although it has been reported in humanitarian aid workers and more recently in persons visiting and working in Haiti following the earthquake in 2010. As more young adults participate in community service projects in at-risk countries, these travelers may benefit from counseling and medications for self-treatment to be used if signs and symptoms develop while abroad. Clinicians should check CDC Travelers' Health website (see resources) for updated country-specific recommendations.

Tables 231-1 and 231-2 provide general guidelines and indications for the use of routine and selected travel-related vaccines based on U.S. recommendations.[53,57,83,88-90,121] WHO recommendations may differ.[156] Depending on the complexity of the travel itinerary and the patient's medical history, the vaccination plan may need to be developed in consultation with a travel medicine or infectious disease specialist. Travel-related vaccine recommendations should be tailored carefully to the trip itinerary and based on the travel destination, season when the travel will occur, duration of the trip, and activities to be undertaken.

Yellow fever occurs year-round in the predominantly rural areas of sub-Saharan Africa and South America; however, outbreaks have been increasing in incidence, particularly in Africa.[154] Infection occurs primarily via the bite of an infected mosquito, usually *Aedes* or *Haemagogus* spp. Transmission occurs in a human-to-vector-to-human cycle with monkeys, mosquitoes, and humans in three patterns: sylvatic (jungle), intermediate (savannah), and urban transmission. The resurgence of yellow fever in urban areas, in association with *Aedes aegypti* mosquitoes, has raised concern about increased risk in Brazil and urban areas of Latin America.[53,141,142] Although a rare disease, yellow fever continues to be reported in travelers, particularly unvaccinated travelers, and is usually fatal. From 1970 through 2010, nine cases of yellow fever were reported in unvaccinated travelers from the United States and Europe who traveled to West Africa (five cases) or South America (four cases); eight (88%) of these travelers died. One case of yellow fever in a vaccinated traveler, who survived infection has been reported.[53,108] The risk for transmission is lower in South America than Africa because travelers are less likely to come in contact with monkeys in the forest canopy. Preventive measures taken against yellow fever should include the use of personal protection against mosquitoes and vaccination. As discussed previously, some countries require yellow fever vaccination for travelers arriving from endemic regions; current requirements and recommendations for vaccination based on travel destination can be obtained from the CDC Travelers' Health website. Yellow fever vaccine is largely considered to be a safe and effective vaccine. However, the vaccine has been found to be associated with an increased risk for development of yellow fever vaccine–associated neurologic disease (YEL-AND), which includes meningoencephalitis, Guillain-Barré syndrome, and other severe reactions in young infants.[121]

Text continued on p. 3106

TABLE 231-1 **Routine Childhood Vaccinations and Accelerated Schedules and Modifications for Pediatric Travelers**

Vaccine	Minimum Age	Routine Schedule*	Accelerated Schedule and Modifications†	Indications for Use and Other Information‡
DTaP, DT	6 wk	5 doses at ages 2, 4, 6, 15-18 mo and 4-6 yr	5 doses MI from dose 1 to dose 2: 4 wk MI from dose 2 to dose 3: 4 wk MI from dose 3 to dose 4: 6 mo Minimum age for dose 4: 12 mo MI from dose 4 to dose 5: 6 mo Minimum recommended age for dose 5: 4-6 yr Dose 5 is not necessary if dose 4 was administered after the fourth birthday	Use for children 6 wk–7 yr of age. Use DT for children <7 yr of age for primary series (instead of DTaP) when pertussis vaccination is contraindicated. The fourth dose may be administered as early as age 12 mo, provided at least 6 mo have elapsed since the third dose.
Tdap	10-11 yr, depending on brand	One dose		Only 1 dose of Tdap is recommended. All subsequent doses of tetanus-diphtheria booster should be administered as Td. Tdap should be substituted for a single dose of Td in the catch-up series for children 7-10 yr. If additional doses are needed, use Td. Tdap can be administered regardless of the interval since the last tetanus and diphtheria toxoid–containing vaccine.
Td	7 years	1 booster dose every 10 yr Children ≥11 yr should receive 1 dose of Tdap, followed by booster doses of Td every 10 yr.	MI for booster for travel: 5 yr	Td should be used rather than Tdap if Tdap is not available and for: Anybody who has already received Tdap Additional doses for children 7-10 yr in the catch-up series (one dose of Tdap should be administered) See information for Tdap regarding timing of Td vs. Tdap.
Haemophilus influenzae type b (Hib)	6 weeks	4 doses at ages 2, 4, 6, and 12-15 mo *or* 3 doses at ages 2, 4, and 12-15 mo (PRP-OMP vaccines only) Unvaccinated child >15 mo: 1 dose	Accelerated schedule is available but varies by vaccine brand; see package insert for vaccine used. MI between doses: 4-8 wk	MI between doses depends on age. Children receiving the first dose of vaccine at age ≥7 mo require fewer doses to complete the series. See *MMWR Morb Mortal Wkly Rep* 2005;**54**:Q1-4, for indications. Vaccinate all children <5 yr of age and children >5 yr of age with special indications (e.g., asplenia, immunodeficiency).

Continued on following page

TABLE 231-1 **Routine Childhood Vaccinations and Accelerated Schedules and Modifications for Pediatric Travelers** (Continued)

Vaccine	Minimum Age	Routine Schedule*	Accelerated Schedule and Modifications†	Indications for Use and Other Information‡
Hepatitis A	1 yr	2 doses at ages 12 and 18 mo	MI from dose 1 to dose 2: 6 mo	Recommended for all children at 1 yr (12-23 mo). Recommended for unvaccinated children ≥24 mo at high risk (see *MMWR Morb Mort Wkly Rep* 2006;**55**[RR-7]), and anyone ≥24 mo, previously unvaccinated, for whom immunity against hepatitis A virus infection is desired. Recommended for all persons ≥12 mo traveling to endemic areas, including Mexico, Central and South America, Asia (except Japan), Africa, and eastern Europe.§ Immunogenicity: limited data are available for the timing of the appearance of neutralizing antibody. Among a sample of vaccinated persons, 54%-62% were positive for neutralizing antibody 14 days after the first dose, and 94%-100% were positive at 1 mo.‡
Hepatitis B¶	Birth	3 doses at 0-2, 1-4, 6-18 mo For children not previously vaccinated: 3 doses at 0-, 1-, and 4-mo intervals For unvaccinated adolescents 11-15 yr: 2-dose vaccine series (only Recombivax HB, adult dose) at 0, 4-6 mo or 3 doses of other vaccine brands	3 doses (except 2 doses of Recombivax HB, adult dose for adolescents) MI from dose 1 to dose 2: 4 wk MI from dose 2 to dose 3: 8 wk MI from dose 1 to dose 3: 16 wk Minimum age for dose 3: 6 mo	Use for travelers to endemic areas, including Africa, Asia, Latin America, who plan to: Travel abroad for ≥3 mo Have intimate or sexual contact with local population Work in health care setting or may have contact with blood, blood products, or body fluids Count all doses; do not restart series even if time lapse between doses is greater than recommended interval. Accelerated schedule: 4 doses at 0, 7, 21-30 days and booster at 1 yr

Human papillomavirus vaccine (HPV)	9 yr For females and males 9-26 yr. Use HPV4 or HPV2 for females and HPV4 for males.	3 doses at 11-12 yr at 0-, 2-, and 6-mo intervals	Recommended interval dose 1 to dose 2: 1-2 mo MI dose 1 to dose 2: 4 wk Recommended interval dose 1 to dose 3: 6 mo Recommended interval dose 2 to dose 3: 4 mo MI dose 2 to dose 3: 3 mo	
Influenza, trivalent inactivated vaccine (TIV) or live attenuated vaccine (LAIV)	TIV: 6 mo; however, check product because minimum age varies by vaccine manufacturer LAIV: 2 years, approved for use only for persons 2-49 yr	Recommended annually for children ≥6 mo. LAIV should not be administered to some children with certain medical conditions. See *MMWR Recomm Rep* 2010;**59**(RR-08):1-62. Children aged 6 mo–8 yr of age who are receiving influenza vaccine for first time: 2 doses Children >8 yr and persons who previously received influenza vaccine: 1 dose	TIV: MI dose 1 to dose 2: 4 wk LAIV: MI dose 1 to dose 2: 6 wk	Influenza can occur throughout the year in tropical countries. Peak influenza in temperate regions of the Southern Hemisphere occurs from April through September. In North America, influenza vaccine may not be available during the summer months. Travelers to the Southern Hemisphere should be vaccinated by the spring, if possible. Consider for travelers who are at high risk for complications from influenza for travel to Tropics any time of year Southern Hemisphere from April through September Any destination with large groups of tourists at any time of year Any destination where influenza outbreaks are occurring
Measles, mumps, rubella (MMR)	6 mo	2 doses at ages 12-15 mo and 4-6 yr	Children 6-11 mo: 1 dose, then revaccinate at 12-15 mo and 4-6 yr of age Children >12 mon vaccinated with 1 prior dose: 1 additional dose at least 4 wk after dose 1 Unvaccinated children >12 mo: 2 doses separated by 4 wk MI between doses: 4 wk	Do not administer MMR for 3 mo after immunoglobulin for hepatitis A prophylaxis; see *MMWR Morb Mortal Wkly Rep* 2005;**54**:Q1-4, for deferral times for blood products and immunoglobulin administered for other indications. Defer immunoglobulin administration for 2 wk after MMR vaccination. Monovalent vaccines are available for measles, mumps, and rubella. Combination MMRV (measles-mumps-rubella-varicella vaccine) can be used for children 12 mo–12 yr but is associated with higher risk for fever and febrile seizures 5-12 days after the first dose among children 12-23 mo.

Continued on following page

TABLE 231-1 **Routine Childhood Vaccinations and Accelerated Schedules and Modifications for Pediatric Travelers** (Continued)

Vaccine	Minimum Age	Routine Schedule*	Accelerated Schedule and Modifications†	Indications for Use and Other Information‡
Meningococcal (quadrivalent A, C, Y, W135) Conjugate vaccine (MCV4) Polysaccharide vaccine (MPSV4)	MCV4-D (Menactra): 9 mo MCV4-CRM (Menveo): 2 yr MPSV4: 3 mo for serogroup A protection, standard recommended minimum age: 2 yr (see indications)	MCV4-D or MCV4-CRM: routine vaccination, 1 dose for children at age 11-12 yr and booster at 16 yr. Administer 1 dose at 13-8 yr of age if not previously vaccinated. MCV4-D: 2 doses for travelers to risk areas ideally at 9 and 12 mo or at least 8 wk apart for children 9-23 mo MCV4-D or MCV4-CRM: 2 doses for travelers to risk areas at least 8 wk apart for children 24 mo–10 yr.		Meningococcal vaccination is required for travelers to annual Hajj in Mecca, Saudi Arabia. Vaccination is recommended for travel to sub-Saharan Africa during dry season (December through June) or for travel to any countries where epidemic is occurring. Recommended for all children with certain medical conditions. See *MMWR Morb Mort Wkly Rep* 2011;**60**:72-6.
Pneumococcal conjugate: 7-valent (PCV7) and 13-valent (PCV13)	6 wk	4 doses at ages 2, 4, 6, and 12-15 mo 1 dose for all healthy children 24-59 mo who are not completely vaccinated for age 1 supplemental dose of PCV13 for certain children who received 1 dose of PCV7: (1) all children 14-59 mo and (2) children 60-71 mo with underlying medical conditions	MI between doses: 4-8 wk, depending on age Number of doses varies with age at first dose administered and current age.	MIs between doses depend on age. Children receiving the first dose of vaccine at ≥7 mo require fewer doses to complete the series. Pneumococcal polysaccharide vaccine (PPV23) is routinely recommended for high-risk persons aged ≥2 years. See *MMWR Morb Mortal Wkly Rep* 2010;**59**(RR 11).
Polio-inactivated poliovirus vaccine (IPV)	6 wk	4 doses at ages 2, 4, 6-18 mo and 4-6 yr	Previously unvaccinated children: 3 doses MI between doses: 4 wk Preferred interval between dose 2 and dose 3: 2 mo Minimum age for dose 2: 10 wk Minimum age for dose 3: 14 wk Minimum age for dose 4: 18 wk Previously unvaccinated children <4 yr at completion of dose 3: 4 doses Previously unvaccinated children ≥4 yr at completion of dose 3: 3 doses MI between doses: 4 wk If ≥4 doses are administered before 4 yr, an additional dose should be given at 4-6 yr. The final dose in the series should be administered on or after the 4th birthday and at least 6 mo after the previous dose.	Primary series is recommended for all travelers; booster dose for persons ≥18 yr is recommended for travelers to some areas of Africa, Asia and the Middle East; not routinely recommended for travel to Latin America. Single booster of IPV for previously vaccinated adults confers lifetime immunity. Oral poliovirus vaccine (OPV) is no longer recommended or available in the United States. For use in other countries, the World Health Organization recommends birth as the minimum age of administration. The MI between doses is 4 wk. OPV can be used for children younger than 6 wk traveling to areas with polio transmission.

Rotavirus (RV): RV1 (Rotarix) and RV5 (Rota Teq)	6 wk	RV1: 2 doses at ages 2, 4 mo RV5: 3 doses at 2, 4, and 6 mo	MI between doses: 4 wk; there is no maximum interval between doses. Minimum age for dose 2: 10 wk Minimum age for dose 3: 14 wk	Maximum age for first dose in series is 14 wk, 6 days; and 8 mo, 0 days for final dose in series Can be administered before, concurrently or after administration of immunoglobulin. See CDC website for information about risk for intussusception with rotavirus vaccine
Varicella	12 months	2 doses at 12-15 mo and 4-6 yr	MI between dose 1 and dose 2 for children <13 yr: 12 wk MI between dose 1 and dose 2 for persons ≥13 yr: 4 wk Minimum age for dose 2: 15 mo	Do not administer varicella vaccine for 3 mo after immunoglobulin for hepatitis A prophylaxis; see *MMWR Morb Mortal Wkly Rep* 2005;**54**:Q1-4, for deferral times for blood products and immunoglobulin administered for other indications. Defer immunoglobulin administration for 2 wk after varicella vaccination. Combination MMRV can be used for children 12 mo–12 yr but is associated with higher risk for fever and febrile seizures 5-12 days after the first dose among children 12-23 mo.

*Number of doses and recommended ages. Minimum age is the U.S. recommendation unless otherwise noted. Recommendations in the U.S. schedule may be different from those of the World Health Organization and other countries.

†Number of doses and MI between doses. *NOTE:* Interval represents time to dose.

‡Contraindications: Anaphylactic reaction to prior dose or to any vaccine component or moderate-to-severe acute illness is a contraindication for all vaccines.

§See MMWR Recomm Rep 2006;**55**(RR-7):1-23.

¶Combination hepatitis A–hepatitis B (Twinrix) is available for use in persons ≥18. The vaccine, which is composed of inactivated viral components, is administered intramuscularly. The schedule involves 3 doses at 0, 1, and 6 months. It can be administered at an accelerated schedule of 4 doses at 0, 7, and 21-30 days and 1 year.

DTap, Diphtheria and tetanus toxoids and acellular pertussis, vaccine; *DT,* diphtheria-tetanus (toxoid); *IPV,* inactivated poliomyelitis vaccine; *MI,* minimal interval; *MMR,* mumps, measles, rubella; *PRP-OMP,* PRP-outer membrane protein conjugate vaccine; *Tdap,* tetanus, diphtheria, and pertussis; *Td,* tetanus and diphtheria (toxoid).

TABLE 231-2 **Common Travel-Related Vaccines and Immunoglobulin for Children**

Vaccine*	Vaccine Type	Route	Minimum Age	Primary Series†	Booster or Revaccination‡	Accelerated Schedule	Protection After	General Indications for Use§
BCG	Live attenuated bacteria	ID, SC	Birth	1 dose	None	None	2 months after dose (WHO)	Consider for children <1 yr who will be long-term travelers residing in high-risk areas to protect against meningeal and miliary tuberculosis.
Immunoglobulin	Antibody from pooled human plasma	IM	Birth	1 dose	3-6 mo	None	Immediate	Use to prevent hepatitis A infection in children <1 yr who are traveling to risk areas or for persons departing within 4 wk. Defer MMR and varicella vaccination for 3 mo after IG administered for hepatitis A prevention; defer the administration of IG for hepatitis A prevention for 2 wk after MMR or varicella vaccination. Defer rotavirus vaccine (RV) administration for 6 wk if possible. However, if 6-wk deferral would cause the first dose of RV to be scheduled for age ≥13 wk, a shorter deferral interval should be used to ensure that the first dose of RV is administered no later than age 13 wk.
Japanese encephalitis (IXIARO)	Inactivated virus	SC	1 yr	2 doses on days 0 and 28	yearly Booster: 1 dose	None	7 days after dose 2	Recommended for travelers who plan to spend a month or longer in endemic areas during the JEV transmission season. Consider for short-term travelers (<1 mo) to endemic areas during JEV transmission season if they plan to travel outside of an urban areas and have an itinerary or activities that will increase their risk for JEV exposure; travelers to areas with an ongoing JE outbreak; and travelers to endemic areas who are uncertain of specific destinations, activities, or duration of travel. Not recommended for short-term travelers whose visit will be restricted to urban areas or times outside of a well-defined JEV transmission season.

								Licensed for use in persons ≥17 yr. Options for children <17 yr of age include off-label use of IXIARO, participation in a clinical trial or vaccination with an alternative JE vaccine overseas. See CDC website for further information. Clinicians should review updated data about risk areas because transmission varies by country and season. Destinations with transmission include to selected areas of Asia, Oceania (Australia and Papua New Guinea), Russia, especially long-term travelers to rural, agricultural endemic areas or epidemic regions during seasonal transmission (usually May to September). Mild adverse reactions (headache, myalgia, fatigue, influenza-like illness) reported in 13%-26% of vaccinees. There are no data on the use of IXIARO as a booster dose after a primary series with JE-VAX. Persons who received JE-VAX should receive the primary 2-dose series of IXIARO
Rabies Human diploid cell vaccine (HDCV) Purified chick-embryo cell culture vaccine (PCEC)	Inactivated virus; cell culture derived	IM	United States: None	3 doses at 0, 7, and 21 or 28 days	No boosters or serologic testing recommended for routine international travelers. Boosters and/or serologic testing recommended for high-risk groups. See CDC website for additional information.	None	14 days after dose 3	Use for travelers to rabies-endemic countries. Vaccination is recommended for long-term travel in rural areas or in areas with limited access to health care. Travelers with extensive unprotected outdoor, evening, and nighttime exposure in rural areas, such as backpacking, should consider vaccination even for trips of short duration. Widespread worldwide rabies distribution. See Health Information for Travelers for list of countries that have not reported cases of rabies recently.

Continued on following page

TABLE 231-2 **Common Travel-Related Vaccines and Immunoglobulin for Children** (Continued)

Vaccine*	Vaccine Type	Route	Minimum Age	Primary Series†	Booster or Revaccination‡	Accelerated Schedule	Protection After	General Indications for Use§
								Postexposure vaccination is required even for persons who receive vaccination before exposure. After exposure in vaccinated person: 2 doses at 0, 3 days (no rabies immunoglobulin required) After exposure in unvaccinated person: Rabies immunoglobulin (RIG) (20 IU/kg) plus vaccination with 4 doses at 0, 3, 7, and 14 days. Rabies immunoglobulin can be administered up to and including day 7 of the postexposure prophylaxis series.
Typhoid (ViCPS)	Capsular polysaccharide	IM	2 yr	1 dose	2 yr	None	14 days after dose	Use recommended for travelers to Africa, Asia, and Latin America for long-term stays, travel outside usual tourist destinations, or travelers who desire maximal protection. Patients should be counseled about protective efficacy of vaccine (approximately 50%-74% when studied in endemic areas) and importance of other preventive measures.
Typhoid oral (Ty21a)	Live attenuated bacteria	Oral	6 yr	4 doses at 0, 2, 4, 6 days	5 yr	None	7-10 days after last dose	See indications for typhoid ViCPS. Patients should be counseled about protective efficacy of vaccine (approximately 60%-85% when studied in endemic areas) and importance of other preventive measures.

								Must be swallowed (cannot be chewed) 1 hr before meal, and vaccine must be refrigerated until administration. Do not administer within 72 hr of any antibacterial agent, including doxycycline. Mefloquine, atovaquone-proguanil, and chloroquine can be administered concurrently. Contraindicated for immunocompromised patients
Yellow fever	Live attenuated virus	SC	6 mo	1 dose	10 yr	None	10 days after dose	Use for travelers to selected areas of Africa and South America. Yellow fever has not been reported in Asia; however, some countries require proof of vaccination if the traveler is arriving from a yellow fever–endemic country. Yellow fever vaccination for children 6-9 mo should be discussed with an expert to weigh risk for adverse events against risk for yellow fever. Reports of rare serious adverse events of multiorgan system failure after vaccination. Contraindicated for patients who are immunocompromised or have allergy to eggs.

*Cholera vaccine is not available in the United States. Tick-borne encephalitis vaccine is not available in the United States. It is administered as a 4-dose series at 0, 28-day, 42-day, and 1-yr intervals, with booster doses required every 3 to 5 yr. The vaccine is available in Europe.
†Number of doses and recommended ages and intervals. *NOTE:* interval represents time from dose.
‡Number of doses and recommended ages and intervals.
§Contraindications: Anaphylactic reaction to prior dose or to any vaccine component or moderate-to-severe acute illness is a contraindication for all vaccines.
BCG, Bacille Calmette-Guérin; *CDC,* Centers for Disease Control and Prevention; *ID,* intradermal; *IM,* intramuscular; *JE,* Japanese encephalovirus; *MMR,* measles, mumps, rubella; *SC,* subcutaneous; *WHO,* World Health Organization.

The incidence is 0.8/100,000 doses. The vaccine should not be used in children younger than 6 months of age. It should be used with caution in children 6 to 9 months of age after discussion with a travel medicine expert to weigh the risks and benefits.[53] Two cases of YEL-AND have been reported in children 6 to 8 months of age. Whenever possible, travel to yellow fever–endemic countries should be postponed for children younger than 9 months of age. Medical waivers can be given to children who are too young for vaccination and to those who have other contraindications to vaccination, such as immunodeficiency. Breast-feeding is a precaution for yellow fever vaccination. Three cases of transmission to infants have been associated with breast-feeding. None of the cases had permanent sequelae, but until more information is available, yellow fever vaccination should be avoided in breast-feeding women, if possible. Since 2001, yellow-fever vaccine-associated viscerotropic disease (YEL-AVD), life-threatening severe illness with major organ system failure similar to wild-type disease has been reported in more than 50 confirmed and suspected cases worldwide. The syndrome usually consists of fever, jaundice, and multiple organ system failure. The case/fatality ratio is 65 percent. The usual onset is 3 days (range, 1 to 8 days) after vaccination. The incidence of YEL-AVD cases in the United States is 0.4/100,000 doses of vaccine administered. The rate is higher in people aged 60 years of age and older, with a rate of 1.0/100,000 doses in people 60 to 69 years of age and 2.3/100,000 doses in people aged 70 years of age and older. The risk is thought to be approximately 1/200,000 to 300,000 doses in persons younger than 60 years and 1/40,000 to 50,000 doses in persons 60 years of age and older. The risk is greater in persons with a history of thymus disorder associated with abnormal immune cell function such as thymoma, myasthenia gravis, or DiGeorge syndrome.[58] Further studies are being conducted.[60,106,141] In the interim, the CDC has recommended that given the risk for serious illness and death from yellow fever,[101] evidence of increasing transmission of the disease,[128] and the known effectiveness of the vaccine, clinicians should continue to use yellow fever vaccine.[53] Health care providers should carefully review travel itineraries to ensure that only people traveling to areas endemic for yellow fever or areas where yellow fever activity is reported receive yellow fever vaccine.[26,29,53,156]

Japanese encephalitis is a viral infection transmitted by *Culex* mosquitoes that bite from dusk to dawn in an enzootic cycle between mosquitoes and vertebrate hosts, primarily pigs and wading birds. Japanese encephalitis is primarily a disease of childhood, with most cases occurring among children younger than 15 years of age. Disease develops in fewer than 1 percent of infected persons.[49] Japanese encephalitis occurs year-round in tropical regions and primarily from May through October in temperate zones. The risk is greatest for travelers to rural Asia, where the mosquito breeds in rice fields and other agricultural areas. Clinicians should consult the CDC Travelers Health website for the current list of areas with endemic and epidemic transmission. Japanese encephalitis is associated with high rates of case fatalities and severe neurologic sequelae, especially in young children and the elderly. Among an estimated 35,000 to 50,000 annual cases worldwide, approximately 20 to 30 percent of patients die, and 30 to 50 percent of survivors have neurologic or psychiatric sequelae.[49] However, Japanese encephalitis is rare among travelers, estimated at less than 1/1 million travelers. During 1973 to 2008, a total of 55 cases of travel-associated Japanese encephalitis among persons from nonendemic countries were reported in the literature. Five (9%) of the cases occurred in children 10 years of age or younger.[53] Expatriates and travelers who stay for prolonged periods in rural areas likely have a risk similar to that of the local population in affected areas (5 to 50/100,000/yr).[53] All travelers to risk areas should use personal protective measures, such as repellent and long-sleeve clothing, to minimize mosquito bites. Vaccination is recommended for travelers who plan to spend a month or longer in endemic areas during the Japanese encephalitis transmission season. Vaccination should be considered for travelers who will spend 30 days or longer in endemic areas during transmission season if they plan to travel outside of an urban area and have an itinerary or activities that will increase their risk for exposure; travelers to an area with an ongoing outbreak; and travelers to endemic areas who are uncertain of specific destinations, activities, or duration of travel. Consider vaccination for short-term travelers (<1 month) to endemic areas during transmission season if they plan to travel outside of an urban areas and have an itinerary or activities that will increase their risk for exposure. Vaccination is not generally recommended for short-term travelers (<30 days) whose visit will be restricted to urban areas or times outside of a well-defined transmission season.[53] Since 2009, one Japanese encephalitis vero culture–derived vaccine, IXIARO, has been licensed for use in children 17 years of age and older in the United States. IXIARO is administered as a two-dose series, with the second dose administered 28 days after the first dose. JE-Vax, an inactivated mouse brain–derived vaccine, was licensed in the United States in 1992 for use in travelers 1 year of age and older. In 2006, JE-Vax production was discontinued, and all remaining doses expired in May 2011. If the primary series of IXIARO was administered 1 year or more previously, a booster dose should be given before potential reexposure or if there is a continued risk for Japanese encephalitis virus infection. No data are available on the use of IXIARO as a booster dose after a primary series with JE-Vax. People who have received JE-Vax previously and require further vaccination against JEV should receive a two-dose primary series of IXIARO. Clinicians should consult the CDC website regarding options for younger children who would benefit from Japanese encephalitis virus vaccination. Other inactivated and live attenuated Japanese encephalitis vaccines are manufactured and used in Asia but are not licensed for use in the United States. Current options include participation in a clinical trial, off-label use of IXIARO, or vaccination in Asia with an alternative Japanese encephalitis vaccine.[53] See Table 231-2 for additional information.

Rabies virus, which causes a progressive fatal encephalomyelitis, occurs worldwide, except in Antarctica. In certain areas of the world, including (but not limited to)

parts of Africa, Asia, and Central and South America, canine rabies remains highly endemic. Rabies also occurs in other wild animals, including bats. The three-dose preexposure rabies vaccine should be considered for children visiting rabies-endemic countries for longer than 1 month, those undertaking extensive outdoor activities such as backpacking or camping in endemic countries, or children traveling to areas where access to health care is limited. Booster doses for persons who completed the three-dose preexposure vaccine series or the full postexposure prophylaxis are considered preimmunized and do not require routine boosters. Routine booster doses and/or serologic testing are recommended for certain high-risk persons working with rabies virus or persons, such as cavers, with frequent exposure to mammals, such as bats. To reduce the risk for acquiring rabies, children and their families should be counseled to stay away from stray dogs and other animals, especially if traveling to Latin America, Asia, or Africa.[53] Exposure is considered a medical emergency. Wound management should include thorough cleansing with soap, water, and povidone-iodine, if available, and suturing delay of a few days, if possible. Postexposure prophylaxis should be administered as soon as possible; travelers who received preexposure vaccination should receive two booster doses on days 0 and 3 after exposure, whereas persons who did not receive preexposure vaccination should receive rabies immunoglobulin and a series of four injections of rabies vaccine over 14 days.[45,50]

Typhoid infection is an acute, life-threatening illness caused by *Salmonella enterica* serotype Typhi, which is usually acquired through contaminated food and water. Vaccination is recommended for pediatric travelers visiting developing countries, especially for prolonged periods, or traveling outside the usual tourist destinations. Travelers visiting friends and relatives are at increased risk. Two vaccines are available in the United States: (1) an attenuated, live oral vaccine that can be administered to children 6 years of age and older and (2) an injectable Vi capsular polysaccharide vaccine that can be administered to children, starting at 2 years of age. The injectable vaccine should be completed 2 weeks or longer before travel, and boosters should be administered every 2 years The oral vaccine consists of four capsules, one taken every other day, and should be completed 1 week before travel. Boosters should be administered every 5 years. Parents should be cautioned, however, that vaccination is not 100 percent effective, and precautions regarding safe food and water should be followed.[53]

PREVENTION OF MALARIA

Epidemiology of Malaria

Malaria is a parasitic infection caused by one of four species of *Plasmodium: Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, or *Plasmodium malariae*. It is transmitted by the bite of an infective female *Anopheles* mosquito. Malaria is endemic in more than 100 countries on five continents; transmission occurs primarily in the tropic and subtropical regions of sub-Saharan Africa, Asia, Latin America, the Caribbean, the Middle East, and Oceania. Globally, malaria is responsible for 250 million clinical infections and nearly 1 million deaths annually, with most caused by *P. falciparum*, principally in young children and pregnant women.[150,153]

An estimated 10,000 to 30,000 travelers from industrialized countries are thought to contract malaria each year, but these numbers probably are underestimated because they do not include travelers in whom malaria was diagnosed and treated abroad.[91,93,103,149] The number of malaria cases reported in 2010 in the United States was the largest since 1980. In 2010, 1691 cases of malaria, including 9 fatal cases, were reported to CDC. All fatal cases were *P. falciparium*, and 7 were acquired in West Africa. Among the 898 cases in U.S. civilians for whom information on chemoprophylaxis use and travel area was known, only 45 (5%) reported that they had followed and adhered to a chemoprophylactic drug regimen recommended by CDC for the areas to which they had traveled. Among the 1573 cases among patients for whom age was known, 232 (15%) occurred in persons younger than 18 years of age. Among the 232 cases among persons younger than 18 years, 108 (47%) occurred among U.S. civilian children, 101 (44%) occurred among children of persons categorized as having a foreign resident status at the time their malaria infection was acquired, and 23 (10%) occurred among children of unknown resident status. Of the 108 cases among U.S. civilian children, 4 (4%) were younger than 24 months, 10 (9%) were 2 to 4 years, 54 (50%) were 5 to 12 years, and 40 (37%) were 13 to 17 years of age. Of these cases among U.S. civilian children for whom country of exposure was known 75 (75%) were attributable to travel to Africa. Among the 83 U.S. civilian children for whom reason for travel was known, 69 (83%) were visiting friends and relatives, 10 (12%) were traveling for educational purposes, 2 (2%) were traveling for missionary work, and 2 were either tourists or specified as other. Of the 85 children for whom chemoprophylaxis information was known, 26 (31%) were reported as having taken prophylaxis, of whom 16 (62%) had taken an appropriate regimen; however, only 5 (31%) of these patients reported adherence.[23]

Reviews of deaths attributed to malaria in the United States indicate that failure to take or to adhere to recommended antimalarial chemoprophylaxis, promptly seek medical case for posttravel illness, and promptly diagnose and treat suspected malaria contributed to fatal outcomes.[30,54,115] Retrospective reviews of malaria in children also have found that a substantial proportion of cases occurred in recent immigrants and the children of former immigrants who had traveled to visit their family's country of origin.[12,83,127] These data highlight the importance of pretravel assessment and counseling, particularly for foreign-born persons, who may assume they are protected by natural immunity or do not perceive the risk for acquisition of malaria by their children who accompany them on returning to visit their home country. The CDC recommends that prevention messages directed toward Africa-bound travelers, particularly those whose destination is West Africa, should be emphasized in early spring, accompanied with a reminder in late fall through early winter. Malaria prevention messages directed

toward Asia-bound travelers, specifically those bound for India, should be intensified in late spring.[54]

Preventing Malaria in Pediatric Travelers

The substantial proportion of U.S. civilian malaria cases reported in children younger than 18 years of age underscores the importance of pretravel counseling and strategies for malaria prevention. Young children and nonimmune persons of any age are at greater risk for development of severe complications from malaria. Prevention of malaria in pediatric travelers depends first on obtaining current and accurate information about the risk for acquiring malaria in proposed travel destinations and determining whether planned activities, such as rural versus urban travel, and the season of travel place the traveler at increased risk for exposure. Information on the geographic- and country-specific risks for acquiring malaria is available from multiple sources. Selected websites with information about the country-specific risk for acquiring malaria are listed in this chapter in the discussion on international travel information resources.

After a thorough assessment of the risk for acquiring malaria has been made, prevention strategies for pediatric travelers are twofold: personal protection measures against contact with mosquitoes and antimalarial chemoprophylaxis. The first mainstay of prevention of malaria is appropriate and effective use of personal protection measures. All travelers to malaria-endemic areas should be counseled on recommended measures to avoid bites from *Anopheles* mosquitoes, which typically are evening and nighttime feeders. Such measures include wearing clothing that reduces the amount of exposed skin (e.g., long-sleeved shirts, long pants tucked into socks, hats, stroller nets) and, whenever possible, remaining in well-screened or enclosed air-conditioned areas. Travelers staying overnight in facilities without air conditioning or screens should use insecticide-treated mosquito nets over the beds. Stroller nets can be used for children in strollers. Bed nets that have been treated with insecticide such as permethrin are more effective in preventing malaria than are untreated bed nets and are safe for children.[116] Travelers can purchase permethrin to spray on the bed nets or purchase pretreated (or impregnated) bed nets. Permethrin also can be sprayed on clothing, but it should not be applied directly to skin. Permethrin remains effective through multiple washings. Clothing and bed nets should be retreated according to the product label. Permethrin should not be applied to the skin. Although permethrin provides longer duration protection, recommended repellents that can be applied to skin (DEET [*N*,*N*-diethyl-*m*-toluamide], picaridin, oil of lemon eucalyptus [OLE], or *para*-menthane-3,8-diol (PMD, the synthesized version of OLE), and IR3535 can also be used on clothing and mosquito nets. During the evening, insecticide also can be sprayed inside rooms.

Another important focus of counseling for personal protection measures is appropriate use of insect repellent on exposed skin. The CDC recommends the use of repellent products with active ingredients registered with the U.S. Environmental Protection Agency (EPA). Products containing the following active ingredients provide long-lasting protection (DEET, picaridin (KBR 3023), IR3535, and OLE or PMD), the synthesized version of OLE. Note that "pure" oil of lemon eucalyptus (essential oil) is not the same product as OLE insect repellent. Some controversy has occurred regarding the recommended concentration of DEET for pediatric use. In 1998, the EPA conducted an extensive review of DEET safety. The agency concluded that no evidence indicates that DEET is toxic to infants or children. Additional evaluations have not demonstrated a link between seizures and topical use.[16,53]

Most repellents can be used on children older than 2 months of age, with the following considerations: (1) products containing OLE specify that they should not be used on children younger than 3 years; (2) repellent products must state any age restriction (if none is stated, the EPA has not required a restriction on the use of the product); and (3) many repellents contain DEET as the active ingredient. DEET formulations of up to 50 percent can be used for children older than 2 months. The concentration of DEET affects the duration of protection. Higher concentrations provide longer protection; however, the duration of protection reaches a plateau at approximately 30 to 50 percent. Therefore, most clinicians recommend products having up to 30 percent for children. The American Academy of Pediatrics recommends that 30 percent or lower DEET should be used on children over 2 months of age and repellents with DEET should not be used on infants younger than 2 months.[4] In a laboratory study, a product with 23.8 percent DEET provided an average of 5 hours of protection (range, 3 to 6 hours) and a product with 6.65 percent DEET provided an average of 2 hours of protection (range, 1.5 to 2.8 hours). Duration of protection may be affected by the environmental temperature, sweating, and wind conditions.[16,26,72,76] Products that contain repellents and sunscreen generally are not recommended because of the need to reapply sunscreen more frequently than repellent.[4,5,113] Mosquito coils should be used with extreme caution in the presence of children to avoid burns and inadvertent ingestion.[21]

Clinicians are encouraged to stress to parents and children alike the importance of using personal protection measures. Despite the demonstrated efficacy of these measures, studies have found that only 17 percent of adult travelers with malaria reported using insect protection methods and only 11 percent took the recommended chemoprophylaxis.[93]

The second mainstay of malaria prevention is chemoprophylaxis. Selection of the appropriate drug for antimalarial chemoprophylaxis must be based on numerous factors: the most recent information available about malaria in the proposed travel destinations; the trip itinerary; the age, weight, and medical history of the traveler; the personal preference for the frequency of dosing and the duration of chemoprophylaxis on return from the trip; and the cost of medication. These decisions can be challenging for primary care providers and clinicians with limited experience in infectious disease and travel medicine, so when in doubt, clinicians should seek the advice of a travel medicine or infectious disease expert. In

addition, the CDC provides resources with guidance on appropriate use of and recommended regimens for antimalarial chemoprophylaxis (listed in the section on international travel information resources).

Figure 231-1 outlines an algorithm for determining appropriate antimalarial chemoprophylaxis regimens for pediatric travelers. Because data on the distribution of drug-resistant malaria are evolving constantly, clinicians always should obtain the most recent information about the risk for malaria and zones of drug resistance from the CDC website or other sources of information before prescribing malaria chemoprophylaxis.[43,53,131]

The first decision point in selecting appropriate antimalarial chemoprophylaxis is whether travel is occurring in a region of chloroquine-sensitive or chloroquine-resistant malaria. For travel to areas with chloroquine-sensitive malaria, chloroquine is the drug of choice for antimalarial chemoprophylaxis. *P. ovale*, *P. malariae*, and most *P. vivax* are widely sensitive to chloroquine; however, chloroquine-resistant *P. vivax* is an emerging problem and has been reported from Guyana, Papua New Guinea, India, Burma (Myanmar), and areas of Indonesia.[51,93] In addition to chloroquine-resistant *P. vivax*, chloroquine-resistant *P. falciparum* has been reported from these areas, and consequently chloroquine would not be recommended as chemoprophylaxis for travelers to these regions.

If the traveler is visiting a region with chloroquine-resistant malaria, the next decision point is whether travel will include regions with chloroquine-resistant malaria only or both chloroquine- and mefloquine-resistant malaria. Chloroquine-resistant *P. falciparum* is widespread and exists in all malaria-endemic areas except Mexico, the Caribbean, Central America west of the former Panama Canal Zone, and some parts of the Middle East and China.[53,92] In some regions, *P. falciparum* may be resistant to both chloroquine and mefloquine; these areas currently are limited to the borders of Thailand with Myanmar (Burma) and Cambodia, the western provinces of Cambodia that border Thailand, and the eastern states of Myanmar (Burma) on the border between Burma and China, along the borders of Laos and Burma, the adjacent parts of the Thailand-Cambodia border, and southern Vietnam.[53,92] For travel to areas with chloroquine-resistant malaria, three current antimalarial chemoprophylaxis options are mefloquine (Lariam), atovaquone-proguanil (Malarone), and doxycycline. The CDC no longer recommends the use of chloroquine-proguanil for

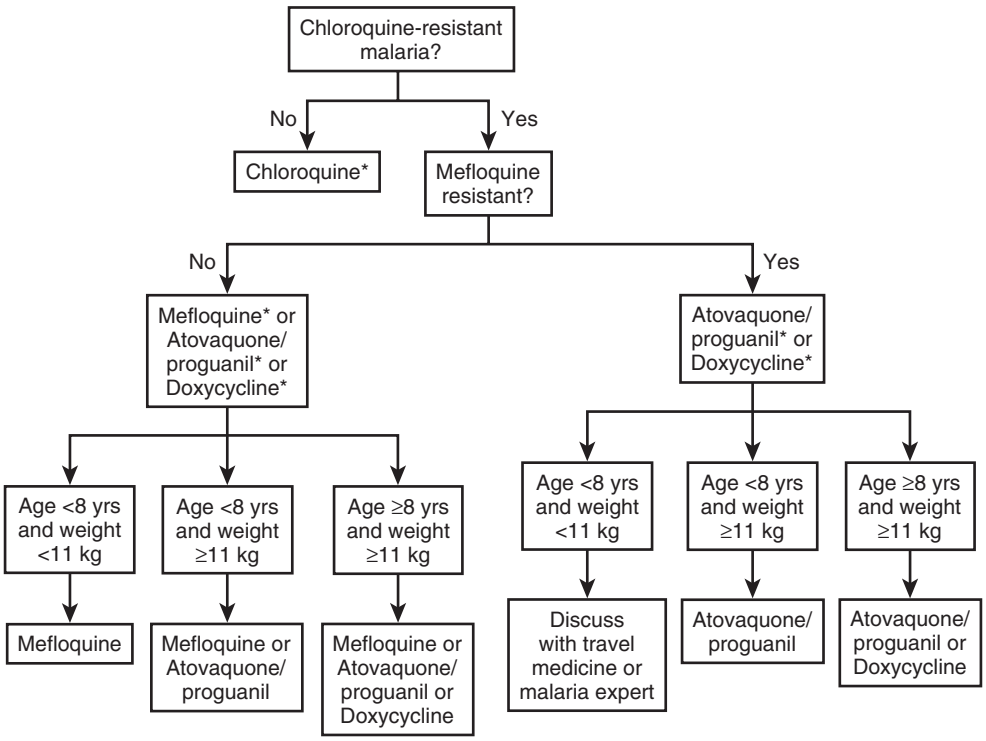

FIGURE 231-1 ■ Algorithm for determining appropriate antimalarial chemoprophylaxis regimens for pediatric travelers.

chemoprophylaxis in chloroquine-resistant areas. For travel to areas with chloroquine-resistant and mefloquine-resistant malaria, either atovaquone-proguanil or doxycycline can be used. Primaquine can be used as an option for primary prophylaxis in special circumstances. Clinicians should contact the CDC Malaria Hotline (770-488-7788 or 1-855-856-4713) for additional information. Primaquine also can be used for terminal prophylaxis to prevent relapses of *P. vivax* or *P. ovale*. In general, terminal prophylaxis is indicated only for persons who have had prolonged exposure to malaria-endemic areas (e.g., missionaries and expatriates).[53]

In evaluating options for antimalarial chemoprophylaxis, physicians should review each medication for contraindications and weight and age restrictions (Table 231-3). Pediatric doses of medications used for treatment should be calculated on the basis of body weight. Medications used for infants and young children are the same as those recommended for adults, except under the following circumstances: doxycycline should not be given to children younger than 8 years of age because of the risk for teeth staining, and atovaquone-proguanil should not be used for prophylaxis in children weighing less than 5 kg because of lack of data on safety and efficacy.

Chloroquine is relatively well tolerated in children. In the United States, chloroquine is available in tablet form; in Europe and other countries, it is also available as a syrup. Mefloquine can be used safely in children weighing less than 9 kg and may be useful for longer trips because it is administered once weekly.[104] However, it must be continued for 4 weeks after leaving the malarious area and no liquid preparation is available. Doses for children are one fourth, one half, and three fourths of a tablet, depending on weight. Mefloquine has been associated with rare but serious adverse reactions (e.g., psychoses and seizures) at prophylactic doses; these reactions are more frequent with higher doses used for treatment. Other side effects that have occurred in chemoprophylaxis studies include depression, anxiety disorder, mood changes, panic attacks, and other neuropsychiatric symptoms. Mefloquine is contraindicated in travelers with active depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. It should be used with caution in people with a history of depression or psychiatric disorders. No data are available on the use of atovaquone-proguanil in children weighing less than 5 kg; however, studies are in progress. For children who weigh 5 kg or more and are at risk for acquiring chloroquine-resistant *P. falciparum* infection, atovaquone-proguanil can be advantageous for short trips because it is started 1 to 2 days before the trip commences and can be stopped 7 days after the trip. However, the patient or parent must remember to take or to administer the medication daily. It is available in pediatric tablet form. Doxycycline is contraindicated in children younger than 8 years because of concern about the propensity of tetracyclines to stain growing teeth or potentially affect developing bones. For older children, doxycycline must be administered daily and continued for 4 weeks after departing the malaria-endemic area.[53,92]

Chloroquine, mefloquine, and atovaquone-proguanil have a bitter taste. Before departure, pharmacists can be asked to pulverize tablets and prepare gelatin capsules with calculated pediatric doses. Mixing the powder in a small amount of food or drink can facilitate the administration of antimalarial drugs to infants and children. Additionally, any compounding pharmacy can alter the flavoring of malaria medication tablets so that they are more willingly ingested by children. Assistance with finding a compounding pharmacy is available on the International Academy of Compounding Pharmacists' website (http://www.iacprx.org). Because overdose of antimalarial drugs, particularly chloroquine, can be fatal, medication should be stored in childproof containers and kept out of the reach of infants and children.

The importance of determining appropriate antimalarial chemoprophylaxis regimens for travelers and counseling to improve compliance cannot be overemphasized. In retrospective reviews of pediatric malaria cases, between 75 and 100 percent of infected children had received inadequate or no chemoprophylaxis.[53,127,143] Finally, effective pretravel malaria prevention counseling includes anticipatory guidance for parents about recognition of and response to symptoms of malaria infection in young pediatric travelers. Parents should be counseled that although compliance with personal protection measures and chemoprophylaxis will decrease the risk, it cannot guarantee prevention of malaria infection. They should be instructed about the symptoms of malaria infection, such as fever, headache, vomiting, diarrhea, and myalgia, and be counseled to seek immediate medical attention if symptoms occur. Delay in recognition and treatment of malaria is associated directly with an increase in rates of morbidity and mortality; therefore, prompt and appropriate initiation of effective therapy is paramount.* Parents also should be advised that some types of malaria can become symptomatic several weeks to months after exposure and therefore prompt medical attention should be sought even if illness develops in a child months after international travel to malaria-endemic areas.

PREVENTION OF TRAVELER'S DIARRHEA IN CHILDREN

Epidemiology of Traveler's Diarrhea

One of the most difficult tasks faced by international travelers of any age is ensuring the safety of food and water. Traveler's diarrhea, caused by the ingestion of contaminated food and water, typically is defined as the occurrence of four or more unformed stools in a 24-hour period or three or more unformed stools in an 8-hour period with at least one of the following signs or symptoms: temperature higher than 38.0° C (100.4° F), abdominal cramping, nausea, vomiting, fecal urgency, tenesmus, or blood or mucus in stools.[68,70,120] Traveler's diarrhea affects approximately 20 to 50 percent of adult travelers and is the health problem most frequently

*References 53, 78, 91, 93, 134, 149.

TABLE 231-3 **Antimalarial Chemoprophylaxis Regimens for Pediatric Travelers**

Medication	Regimen	Dose	Contraindications and Precautions	Side Effects	General Indications and Information for Use
Chloroquine (Aralen)	Weekly starting 1-2 wk before trip Continue weekly during trip and for 4 wk after trip	5 mg base/kg (8.3 mg salt/kg) up to 300 mg base (500 mg salt) Tablets: 300 mg base (500 mg salt)	Prior retinal or visual field changes Psoriasis (may be exacerbated by chloroquine)	Gastrointestinal symptoms, seizures, rash headache, dizziness, pruritus (especially in dark-skinned persons), blurred vision, decreased hearing, tinnitus, retinal damage at high cumulative doses* High toxicity in overdoses, keep out of reach of children	Use only in areas of chloroquine-sensitive malaria Limited usefulness because of widespread chloroquine resistance Bitter taste
Mefloquine (Lariam)	Weekly starting 1 week before trip Continue weekly during trip and for 4 wk after trip	≤9 kg: 4.6 mg/kg base (5 mg/kg salt) 15-19 kg: ¼ tablet 20-30 kg: ½ tablet 31-45 kg: ¾ tablet ≥46 kg: 1 tablet Tablets: 228 mg base (250 mg salt)	Psychiatric conditions, cardiac conduction disorders, seizure disorders, persons with known hypersensitivity to mefloquine Should not take with quinine-like drugs	Gastrointestinal symptoms, dizziness, insomnia Occasional serious adverse effects: seizures, nightmares, depression, anxiety, psychosis, especially in persons with these preexisting medical conditions	Use in areas with chloroquine-resistant malaria Advantageous for long-term travelers because of weekly dosing and less costly than atovaquone-proguanil. Bitter taste
Atovaquone-proguanil (Malarone)	Daily starting 1-2 days before trip Continue daily during trip and for 7 days after trip	5-8 kg: 1/2 pediatric tablet (62.5 mg atovaquone/25 mg proguanil hydrochloride) 9-10 kg: 3/4 pediatric tablet 11-20 kg: pediatric tablet ≥40 kg: 1 adult tablet (250 mg atovaquone and 100 mg proguanil hydrochloride) Pediatric tablets: 62.5 mg atovaquone and 25 mg proguanil hydrochloride Adult tablets: 250 mg atovaquone and 100 mg proguanil hydrochloride	Contraindicated in severe renal failure Not recommended or use with caution for children <11 kg, pregnant or lactating women Do not take with tetracycline, metoclopramide, rifampin, or rifabutin (all reduce concentrations of atovaquone)	Gastrointestinal symptoms, headache, loss of appetite, dizziness, pruritus	Use in areas with chloroquine-resistant or mefloquine-resistant malaria. Advantageous for short-term travelers because prophylaxis can be stopped 1 week after leaving malaria area. Available in pediatric tablets. Take with food or milk.
Doxycycline	Daily starting 1-2 days before trip Continue daily during trip and for 4 wk after trip	2 mg/kg up to 100 mg daily Tablets: 50 mg, 100 mg	Do not use for children <8 yr, pregnant or lactating women Do not give within 3 hr of antacids, iron or Pepto-Bismol Do not administer oral typhoid vaccine within 72 hr of doxycycline	Gastrointestinal symptoms, photosensitivity, increased blood urea nitrogen level, hypersensitivity reactions, blood dyscrasias, vaginal candidiasis May decrease the effectiveness of oral contraceptives	Use in areas with chloroquine-resistant and mefloquine-resistant malaria (borders of Thailand with Myanmar (Burma) and Cambodia, the western provinces of Cambodia that border Thailand, and the eastern states of Myanmar (Burma), on the border between Burma and China, along the borders of Laos and Burma, the adjacent parts of the Thailand-Cambodia border, and in southern Vietnam. Take with food; taking with food or milk can decrease gastric irritation (absorption of doxycycline is not significantly decreased by simultaneous administration of milk or food).

*Despite the use of chloroquine as an antimalarial chemoprophylaxis agent for decades and the use of high-dose chloroquine for certain chronic diseases, the literature is inconclusive about the potential risk for retinopathy associated with long-term use of chloroquine for antimalarial prophylaxis. Retinopathy has rarely been reported in patients receiving weekly prophylaxis. Retinopathy appears to be related to dosage and accumulated dosage.

reported by travelers to developing countries.[67,68] It can occur any time during travel but typically occurs within the first week or two of the trip. The illness usually is self-limited, and for adults the average duration of illness has been reported to be 3 to 5 days.[70] Less information about traveler's diarrhea in children is known and the studies show conflicting data about whether certain age groups are more affected. In a recent prospective study among 152 children 2 to 18 years of age and their parents from the Netherlands, one third of the children experienced diarrhea during international travel and, of these, 30 percent graded their illness as moderate or severe. Of 328 children who sought care for travel-associated illness at the emergency room of the University of Zürich Children's Hospital, 129 (39%) had a diarrheal illness, including 3 with *Salmonella typhi* and 2 with *Salmonella paratyphi* infection. The proportion of children with diarrhea increased with age—33 percent in children age 0 to younger than 2 years, 39 percent in children age 2 to 5 years and younger, and 45 percent in children 6 to 16 years. Among the ill pediatric travelers visiting family and relatives, 41 percent had diarrhea.[85] In a study of 890 children younger than 20 years of age presenting to the outpatient travel clinic of the University of Munich after travel to the tropics and subtropics and their associates, 25 percent had acute diarrhea, the most frequent syndrome among all ill travelers. The most frequently diagnosed infectious enteric pathogens were giardiasis (8%), *Camplylobacter* enteritis (4%), *Salmonella* enteritis (4%) and amebiasis (3%).[82] A retrospective study of Swiss children who had visited the tropics or subtropics reported finding similar incidence rates of traveler's diarrhea in children—40.0, 8.5, 21.7, and 36.0 percent in children aged 0 to 2, 3 to 6, 7 to 14, and 15 years and older, respectively. In this study, the authors also found that small children (0 to 2 years old) most frequently were affected with traveler's diarrhea and that the clinical course tended to be more severe and prolonged than in older pediatric age groups. Overall, children were found to have longer lasting illness than that noted in adults, with an average duration of 11 days for all children combined and 29 days for small children.[122]

Enteric pathogens typically are isolated from approximately 50 to 75 percent of stool specimens from adult travelers with diarrhea; in the remainder, usually no pathogen is isolated. *Escherichia coli*, especially enterotoxigenic *E. coli*, is the most common overall cause of traveler's diarrhea (although the incidence can vary by destination), followed by *Campylobacter*, *Salmonella*, and *Shigella*. Other etiologic agents include pathogenic bacteria, such as *Aeromonas* and *Plesiomonas;* protozoa (e.g., *Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium* spp., and *Cyclospora cayetanensis*); viruses, such as rotavirus and Norwalk-like viruses; and, rarely, helminths.[120] Numerous risk factors for traveler's diarrhea, including the consumption of certain high-risk foods (i.e., raw foods such as meats, seafood, and vegetables; unpasteurized dairy products; and ice and tap water) and travel to certain destinations, also have been identified.[133] Other authors previously categorized destinations by high, intermediate, and low levels of risk for acquiring traveler's diarrhea. Destinations generally considered to have the highest associated risk for contraction of traveler's diarrhea include most of Asia, Africa, Mexico and Central and South America; destinations with intermediate risk include Eastern Europe, South Africa and some of the Caribbean islands; and low-risk travel destinations include countries in North America, Northern and Western Europe, Australia, New Zealand, and Japan.[53] The location of food preparation also is a recognized risk factor for acquiring traveler's diarrhea, with a higher risk shown for travelers eating from street vendors and in local restaurants and a lower risk in luxury hotels and private homes. Although fewer data on traveler's diarrhea in children are available, children (especially toddlers) are probably more vulnerable to foodborne and waterborne pathogens for many reasons, including their propensity to touch multiple surfaces and to mouth objects. Of note, one study found that only 40 percent of parents said that they had practiced dietary prevention measures consistently and only 5 percent reported using oral rehydration solutions (the mainstay of treatment of diarrhea in children).[122]

Preventive Counseling for Traveler's Diarrhea

Counseling parents of pediatric travelers about appropriate preventive behavior to avoid traveler's diarrhea and anticipatory guidance to ensure successful management of diarrhea are important aspects of the pretravel assessment.

Food and Beverage Precautions

The most important aspect of preventive counseling for parents of pediatric travelers is appropriate food and beverage precautions. In addition to preventing the diarrheal diseases already listed, compliance with food and water precautions also will decrease the risk for contracting other foodborne diseases such as hepatitis A. Parents should be counseled that in areas where chlorinated tap water is not available or where hygiene and sanitation are poor, tap water (including ice cubes) should be considered contaminated and hence should be avoided. In addition, travelers also should be advised to avoid brushing their teeth with tap water. Breast-feeding, boiled or bottled water, and bottled carbonated beverages are recommended as typically safe beverages for children; powdered drink mixes made with boiled water (e.g., formula or tea) also generally can be considered safe. Parents should dry wet cans and bottles before opening and wipe drinking surfaces clean before serving.[90]

In areas where access to bottled water is poor, water may be boiled for 1 minute (or for 3 minutes at altitudes above 2000 m [6562 feet]). These procedures will kill bacterial, parasitic, and viral pathogens. Chemical disinfection with halogens (iodine or chlorine) is an alternative method for water treatment when the water cannot be boiled; however, some common waterborne parasites, such as *Cryptosporidium*, are poorly inactivated by iodine disinfection, even after extended contact time. Chlorine also can be used for chemical disinfection, but its

germicidal activity varies with pH, temperature, and organic content of the water; therefore, it can provide less consistent levels of disinfection in many types of water. Thus, chemical disinfection with iodine or chlorine should be supplemented with filtration to remove these organisms. However, chlorine dioxide, which is more potent than equivalent doses of chlorine, is effective against all waterborne pathogens, is simple to use and available in liquid or tablet form.[53] Tablets for water disinfection are available at pharmacies, sporting goods stores, and camping outfitters. Ultraviolet (UV) light is effective against all waterborne pathogens. Some portable devices are available; however, clear water is required to ensure that the UV rays can reach the pathogens in the water. Portable filters are available and provide various degrees of protection against microbes. Reverse-osmosis filters afford protection against viruses, bacteria, and protozoa, but they are large and expensive, and the small pores can be plugged by cloudy or muddy water. Microstrainer filters with pore sizes in the 0.1- to 0.3-μm range can remove bacteria and protozoa from drinking water, but they do not remove viruses. To kill viruses, parents using microstrainer filters should be advised to chemically disinfect water with iodine after filtration. Data are inadequate at present to evaluate the efficacy of specific brands or models of filters, and therefore the CDC cannot recommend specific brands or models of filters most likely to remove bacteria, viruses, and parasites.[53]

Parents of pediatric travelers also should be counseled on the importance of advance planning for food and beverage items, especially for infants and young children. Breast-feeding infants are considered relatively safe from contracting traveler's diarrhea because they are not exposed to local food and water; therefore, traveling mothers should be encouraged to continue breast-feeding for as long as practical. For infants receiving formula, formula concentrate and powdered forms are the most convenient for travel, but a clean water supply must be available or water must be boiled or chemically disinfected before preparation. For feeding toddlers and older children, the travel adage of "boil it, cook it, peel it, or forget it" applies. In general, unless beverages and food come from a can or can be completely cooked or peeled, they should be considered unsafe (including raw fruits and vegetables). Travelers should avoid unpasteurized dairy products, including cheese and ice cream. In addition, travelers should be advised to not consume raw seafood, shellfish, and meats. Freshly prepared steaming hot food, breads and cereals, hot pasta (including rice and noodles), and well-cooked meat or fish generally can be considered safe for consumption. Bringing crackers and peanut butter is a good suggestion for parents of hungry children when the availability of safe foods is uncertain. The incidence of traveler's diarrhea in children also can be reduced potentially by advising parents to encourage or supervise frequent hand washing, including the use of alcohol-based hand sanitizer, and to try to prevent children from placing objects in their mouths.

Some species of fish and shellfish can contain poisonous biotoxins, such as ciguatoxin and scombrotoxin, even when they are well cooked. Ciguatera poisoning is a potential risk in all subtropical and tropical regions of the West Indies and the Pacific and Indian oceans where the implicated fish are consumed; such fish include barracuda, red snapper, grouper, amberjack, and sea bass. Symptoms of ciguatera poisoning include gastroenteritis and neurologic manifestations such as dysesthesias and weakness. Scombroid poisoning occurs in tropical and temperate regions and is caused by high levels of histidine in the flesh of fish such as bluefin, yellowfin tuna, mackerel, bonito, mahi-mahi, herring, amberjack, and bluefish; if improperly refrigerated, histidine is converted to histamine, which can cause flushing, headache, nausea, vomiting, diarrhea, and urticaria.[53]

Managing Traveler's Diarrhea in Children

Adults traveling with children should be counseled about the signs and symptoms of dehydration and the proper use of WHO oral rehydration solution (ORS). Immediate medical attention is required for an infant or young child with diarrhea who has signs of moderate-to-severe dehydration, bloody diarrhea, temperature higher than 38.5° C (>101.5° F), or persistent vomiting. ORS should be provided to the infant by bottle or spoon while medical attention is being obtained.

Assessment and Treatment of Dehydration

The greatest risk to the infant with diarrhea and vomiting is dehydration. Fever or increased ambient temperature increases fluid losses and speeds dehydration. Parents should be advised that dehydration is best prevented and treated by use of ORS, in addition to the infant's usual food. Rice-based and other cereal-based ORS, in which complex carbohydrates are substituted for glucose, also are available and may be more acceptable to young children. Adults traveling with children should be counseled that sports drinks, which are designed to replace water and electrolytes lost through sweat, do not contain the same proportions of electrolytes as those of the solution recommended by WHO for rehydration during diarrheal illness.

ORS packets are available at stores or pharmacies in almost all developing countries. (See later information about ORS availability in the United States.) ORS is prepared by adding one packet to boiled or treated water. Travelers should be advised to check packet instructions carefully to ensure that the salts are added to the correct volume of water. ORS should be consumed or discarded within 12 hours if it is held at room temperature or 24 hours if it is kept refrigerated. A dehydrated child will drink ORS avidly; travelers should be advised to give it to the child as long as the dehydration persists. An infant or child who vomits the ORS usually will keep it down if it is offered by spoon, oral syringe, or straw in frequent small sips.[51,96,131]

Children weighing less than 10 kg who have mild-to-moderate dehydration should be administered 60 to 120 mL (2 to 4 oz) ORS for each diarrheal stool or vomiting episode. Children who weigh 10 kg should receive

120 to 240 mL (4 to 8 oz) of ORS for each diarrheal stool or vomiting episode. Severe dehydration is a medical emergency that usually requires administration of fluids by intravenous or intraosseous routes.[53,66,95,130]

A dehydrated child will usually drink ORS avidly; travelers should be advised to give it to the child as long as the dehydration persists. As dehydration lessens, the salty-tasting ORS solution may be refused, and another liquid can be offered. An infant or child who has been vomiting will usually keep ORS down if it is offered by spoon or oral syringe in small sips; these small amounts must be offered frequently, however, so the child can receive an adequate volume of ORS. Older children will often drink well by sipping through a straw. Severely dehydrated children, however, often will be unable to drink adequately. Severe dehydration is a medical emergency that usually requires administration of fluids by intravenous or intraosseous routes.

ORS packets are available in the United States from Jianas Brothers Packaging Company.* ORS packets may also be available at stores that sell outdoor recreation and camping supplies. In addition, Cera Products† markets a rice-based, rather than glucose-based, product.

Dietary Modification

Breast-fed infants should continue nursing on demand. Formula-fed infants should continue their usual formula during rehydration. They should receive a volume sufficient to satisfy energy and nutrient requirements. Lactose-free or lactose-reduced formulas usually are unnecessary. Dilution of formula may slow resolution of diarrhea and is not recommended. Older infants and children receiving semisolid or solid foods should continue to receive their usual diet during the illness. Recommended foods include starches, cereals, yogurt, fruits, and vegetables. Foods that are high in simple sugars, such as soft drinks, undiluted apple juice, gelatins, and presweetened cereals, can exacerbate diarrhea by osmotic effects and should be avoided. In addition, foods high in fat may not be tolerated because of their tendency to delay gastric emptying. The practice of withholding food for 24 hours or longer is inappropriate. Early feeding can decrease changes in intestinal permeability caused by infection, reduce illness duration, and improve nutritional outcome. Highly specific diets (e.g., the BRAT [bananas, rice, applesauce, and toast] diet) frequently have been recommended; however, similar to juice-centered and clear-fluid diets, such severely restrictive diets used for prolonged periods can result in malnutrition and should be avoided.[95]

Other Measures

Parents should be particularly careful to wash hands well after changing diapers of infants with diarrhea to avoid spreading infection to themselves and other family members.

Oral syringes available in most pharmacies for oral medications can be useful for the administration of ORS and can be included as part of the traveler's health kit for young children. Straws also can be useful for older children.

Bismuth subsalicylate (BSS), which is the active ingredient in Pepto-Bismol, can be used to prevent travelers' diarrhea in children 12 years of age and older. Studies from Mexico have shown that BSS taken daily as either 2 oz (60 mL) of liquid or two chewable tablets four times per day reduces the incidence of travelers' diarrhea from 40 percent to 14 percent. BSS can cause blackening of the tongue and stool and may cause nausea, constipation, and, rarely, tinnitus. BSS should be avoided by travelers with aspirin allergy, renal insufficiency, and gout and by those taking anticoagulants, probenecid, or methotrexate. In travelers taking aspirin or salicylates for other reasons, the use of BSS may result in salicylate toxicity. BSS is not generally recommended for children younger than 12 years of age; however, some clinicians use it off-label, with caution in certain circumstances. Because of the association between salicylates and Reye syndrome, BSS is not generally recommended to treat diarrhea in children younger than 12 years of age. However, some clinicians use it off-label, with caution in certain circumstances. Caution should be taken in administering BSS to children with viral infections, such as varicella or influenza, because of the risk for Reye syndrome. BSS is not recommended for children younger than 3 years of age. Studies have not established the safety of BSS use for periods longer than 3 weeks.[53] Insufficient data are available at this time to recommend the use of probiotics for the prevention of travelers' diarrhea in children.[53,69]
